The distinguished work by A.A. Abrikosov awarded of the Nobel Prize in Physics for 2003 not only has determined the orientation of all investigations of the mixed state of type II superconductors during forty years but also has provoked a mass delusion. Most scientists consider the Abrikosov state first of all as a vortex lattice. But Abrikosov has found a periodic lattice structure with crystalline long-rang order only because that he searched it. It is impossible to obtain any other result besides a periodical structure for the case of homogeneous, symmetric, infinite space. The long-rang order of superconducting state is phase coherence. It is strange that most scientists have lightly admitted that the Abrikosov state can have two long-rang order although only phase transition is assumed always on the way from this state in the normal state. Moreover, the vortex lattice is considered by many scientists as only long-rang order of the Abrikosov state and therefore vortex lattice melting is one of the most popular themes in physics of superconductors during last 15 years. It is explained in the present paper why the only first order phase transition observed on the way from the Abrikosov state in the normal state can not be interpreted as vortex lattice melting. History of the problem is considered and it is analysed why some delusions about the Abrikosov state became popular. It is emphasized that taking into account thermal fluctuations changes in essence the habitual notion about the mixed state of type II superconductor built because of the Abrikosov result. First of all it shows that the Abrikosov solution is not valid just in the ideal case for which it was obtained. The false concept of vortex lattice melting appeared because of some causes main of them are erroneous interpretation of direct observation of the Abrikosov state and the use by theorists the habitual determination of phase coherence invalid for multi-connected superconducting state.

1. Introduction

The awarding of the Nobel Prize in Physics for 2003 is the well-deserved appreciation of the distinguished work by A.A. Abrikosov published in 1957 [1]. Results of this work determined the orientation of all following investigations of the mixed state of type II superconductors. But it is necessary to note to draw attention on a contradiction of the results [1] which has provoked some delusions. The famous Abrikosov solutions [1], as well as all following solutions [2] obtained in the mean field approximation for an ideal superconductor (i.e. without pinning disorders), predict two long-rang orders in the Abrikosov state: crystalline long-rang order of vortex lattice and long-rang phase coherence. Whereas only second order phase transition was assumed from the normal state to the Abrikosov state at the second critical field, H_{c2} . The situation became more dramatic when the consideration of the thermal fluctuations in the seventies showed that the second order phase transition, assumed during a long time, can not be at H_{c2} because of the reduction of the effective dimensionality of thermal fluctuations on two near H_{c2} [3-7]: two long-rang orders but no transition. The investigations of the thermal fluctuations changed habitual notion about the mixed state formed by the Abrikosov's work.

The lost transition into the Abrikosov state was found first in a bulk superconductor in the early eighties [8]. It was found that this sharp transition is observed below H_{c2} and its position was denoted H_{c4} in [9]. This result was repeated in ten years at investigation of high-Tc superconductors (HTSC) [10-12] and was shown that it is first order phase transition [13,14], but not the second order phase transition predicted by theory [1] obtained in the mean field approximation. But only transition is observed on the way from the normal state into the Abrikosov state in all experimental works, in both conventional and HTSC. What long-rang order does at this only transition appear: crystalline long-rang order, long-rang phase coherence or both?

Only few experts comprehended before the HTSC discovery that taking into account of thermal fluctuations changes qualitatively the notion about the mixed state built by Abrikosov and that the second order phase transition into the Abrikosov state is not observed at H_{c2} . But the situation became even worse after 1986 when many scientists turned their attention to the fluctuation phenomena in the mixed state. The visual model of the Abrikosov state as vortex lattice was more acceptable for them than less visual long-rang phase coherence. Therefore when the first order phase transition from the Abrikosov state was found also in HTSC it was interpreted by most people as vortex lattice melting. This concept is very popular and predominated up to now. But it can not be correct. It assumes that vortex liquid (i.e. a state with vortices and consequently with long-rang phase coherence) exists above the only phase transition observed at H_{c4} . In this case an additional transition should be observed above vortex lattice melting, i.e. above H_{c4} , where the long-rang phase coherence can disappear. As it will be shown below this disappearance should be first order phase transition in superconductor with weak pinning disorders. But because only first order phase transition is observed in all known observation then it is obvious that it is rather long-rang phase coherence disappearance than vortex lattice melting.

The history of the investigation of the Abrikosov state can be used as a confirmation of the wisdom by Richard Feynman that an understanding is a habit. It may be useful for scientists concerned oneself with psychology of the scientific research. This history shows that images and even denomination can influence on a orientation of physical researches. Therefore it is very important to use correct interpretation of images and correct denomination. In order to find what interpretation is correct the history of the problem should be considered. It will be made in the Second Section. Main results obtained during 70 years are considered in this section briefly. Some most important results are considered in the next Sections. Two long-rang orders predicted by Abrikosov are considered in the Third Section. Some images, such as flux line, flux flow resistance and others, appear because of no quite correct interpretation of direct observations of the Abrikosov state. It is explained in the Fourth Section why these images and denominations are not correct. The lowest Landau level approximation is considered in the Fifth Section. According to this approximation of the fluctuation theory valid near H_{c2} the "jump" of the specific heat and the fracture of the magnetization dependence are not connected with the second order phase transition into the Abrikosov state. The problem of the transition into the Abrikosov state in an ideal superconductor and real superconductors with weak pinning disorders is considered in the Sixth Section. It is shown that there is an important difference between tree- and two-dimensional superconductors and that the shape transition into the Abrikosov state is observed only in bulk superconductors with enough weak pinning disorders. It is

explained in the Seventh Section why the transition into the Abrikosov state is smooth in most samples in which pinning disorders are not enough weak and it is emphasized that pinning disorders stabilize the Abrikosov state in thin films and layered superconductors. The stabilization of the Abrikosov state by pinning disorders (including superconductor boundaries) and the influence on it the crystal lattice of the superconductor raise a question about a state in an homogeneous, symmetric, infinite space. It is stated in the Eighth Section that a mixed state without phase coherence should be expected in this ideal case considered by Abrikosov. Some motives of the appearance of the erroneous concept of vortex lattice melting are analysed in the Ninth Section.

2. History of the Mixed State Investigations

The superconductivity is one of the most marvelous phenomenon in physics. A flow without friction, without energy dissipation, is at variance with our everyday experience. But there is a more wonderful effect. Following the discovery of the disappearance of electrical resistance in quicksilver at low temperatures by Kamerlingh Onnes in 1911, a more fundamental aspect of superconductivity has been discovered by Meissner and Ochsenfeld in 1933, when they observed that a superconductor, placed in a weak magnetic field, completely expels the field from the superconducting material except for a thin layer at the surface [15]. This expulsion of a magnetic field generally referred to as the Meissner effect is first and most obvious evidence that superconductivity is macroscopic quantum phenomenon. A profound comprehension of this effect allows to understand many peculiarities of superconductor behaviour including the one considered in this paper.

Complete flux expulsion in the simple form of the Meissner effect takes place only in a weak magnetic field. If the applied field is sufficiently strong and if demagnetization becomes appreciable then magnetic flux penetrates through the superconductor. This penetration is qualitative difference in two types of superconductors having various sign of the wall energy associated with the interface between the normal and superconducting domains. In type-I superconductors the wall energy is positive and therefore the amount of flux contained in a single normal domain is many flux quanta. This domain configuration is called the intermediate state. Type-II superconductors considered in this paper are characterized by a negative wall energy. Therefore in this case magnetic flux can be dispersed through the superconductor in the form of single flux quanta $\Phi_0 = \pi\hbar/e$, the smallest possible quantum unit of magnetic flux. Type-II superconductivity occurs preferentially in alloys, or more generally, in impurity systems. Pure metals usually are expected to display type-I superconductivity.

2.1. The Shubnikov phase.

Type-II superconductors was encountered first in experiment by Shubnikov et al. 70 years ago. These authors investigated the superconducting properties of alloys and

discovery persistent of superconductivity up to unusual high magnetic fields. They found that in contrast to pure superconductors where magnetic flux is completely expelled in the superconducting state and the Meissner effect [15] is established the magnetic flux can penetrate in the alloys without complete destruction of superconductivity [16]. After the Abrikosov's work [17] this unusual behaviour is interpreted in terms of mixed state of type-II superconductors. Because of Shubnikov's early experiments, often the mixed state is also referred to as the Shubnikov phase.

2.2. The Mendelssohn model.

The investigations showed that the magnetization dependence of alloys is rather like to the one of an ideal conductor than of superconductor with its Meissner effect [16]. In order to explain the difference between pure superconductors and alloys Mendelssohn assumed [18] that superconducting region is not continuous in alloys and it is multi-connected structure like superconducting sponge. This model described enough well some properties of type-II superconductors such as penetration of the magnetic field, irreversible magnetization curves, resistive peculiarities and others. But it was neglected when the Abrikosov model became popular. Nevertheless Mendelssohn sponge may be considered as limit case of strong pinning disorder and it is more suitable for the description of the mixed state of real type-II superconductor with strong pinning disorder than the Abrikosov model made for an ideal superconductor without pinning.

2.3. The Ginzburg-Landau theory

The following progress in the investigation of the mixed state is connected with the Ginzburg-Landau (GL) theory [19] awarded the Nobel Prize in Physics for 2003. This theory is based on Landau's theory [20] of second-order phase transition, in which Landau introduced the important concept of the order parameter. In the GL theory the order parameter is a complex quantity, namely a wave function $\Psi(r) = |\Psi|exp(i\varphi)$. The absolute value $|\Psi(r)|$ is connected with the local density of superconducting electrons, $|\Psi(r)|^2 = n_s(r)$. The phase φ of the order parameter is needed for describing supercurrents. The free-energy density f_{GL} is then expanded in powers of $|\Psi(r)|^2$ and $|\nabla\Psi(r)|^2$, assuming that Ψ and $\nabla\Psi$ are small

$$f_{GL} = \alpha(T)|\Psi|^2 + \frac{\beta}{2}|\Psi|^4 + \frac{1}{2m}|\left(\frac{\hbar}{i}\nabla - 2eA\right)\Psi|^2 \quad (1)$$

Here $\alpha(T) = \alpha_0(T - T_c)$ and β are coefficients of the GL theory; α_0 and β are constants > 0 . The minimum energy is found from a variational method leading to a pair of coupled differential equations for $\Psi(r)$ and the vector potential $A(r)$. Following a standard variational procedure, one finds the two Ginzburg-Landau differential equations

$$\alpha(T)\Psi + \beta|\Psi|^2\Psi + \frac{1}{2m}\left(\frac{\hbar}{i}\nabla - 2eA\right)^2\Psi = 0 \quad (2a)$$

and

$$j_s = \frac{2e\hbar}{2mi}(\Psi^*\nabla\Psi - \Psi\nabla\Psi^*) - \frac{4e^2}{m}|\Psi|^2 A \quad (2b)$$

Equation (2) has the form of the Schrodinger equation with the energy eigenvalue $-\alpha$, the term $\beta|\Psi|^2\Psi$ acting like a repulsive potential. Equation (3) represent the quantum-mechanics description of a superconducting current j_s .

The two characteristic lengths: the coherence length $\xi(T) = \hbar/(2m|\alpha|)^{1/2}$ and the penetration depth $\lambda(T) = (m/4e^2|\Psi|^2)^{1/2}$ can be derived from the GL theory. These lengths $\xi(T)$ and $\lambda(T)$ show the same proportionality to $(1 - T/T_c)^{-1/2}$ near the critical temperature T_c . Therefore, it was useful to introduce the Ginzburg-Landau parameter $\kappa = \lambda(T)/\xi(T)$. This parameter is very important: at $\kappa < 1/\sqrt{2}$ the wall energy of a normal-superconducting interface is positive and the superconductor is type-I and at $\kappa > 1/\sqrt{2}$ the wall energy is negative and the superconductor is type II [21].

2.4. The Abrikosov solution.

Since the wall energy of type II superconductor is negative the mixed state can be possible in a magnetic field region. First it was noted by Abrikosov in 1952 [17]. Abrikosov wrote in this work that the normal state becomes unstable at the magnetic field $H < \sqrt{2}\kappa H_c$ and the mixed state can be observed between the first H_{c1} and second H_{c2} critical fields, where H_c is the thermodynamic critical field.

During the first appearance of superconductivity the density of superconducting pairs $|\Psi|^2$ will be small. Therefore, the GL equation can be linearized neglecting the term $\beta|\Psi|^2\Psi$ in (2). The linear equation

$$\frac{1}{2m}(\frac{\hbar}{i}\nabla - 2eA)^2\Psi = -\alpha\Psi \quad (3)$$

resembles the Schrodinger equation of a free particle in a uniform magnetic field, with the energy eigenvalue given by $-\alpha$.

The energy eigenvalues E_n of a free particle in a uniform magnetic field correspond to quantized states of the Landau levels

$$E_n = m\frac{v_z^2}{2} + (n + 0.5)\frac{\hbar 2eH}{m} \quad (4)$$

v_z is the velocity component along magnetic field; n is a positive integer number. The non-zero solution for Ψ can be at $E_n = -\alpha$. Therefore the highest field H satisfying this equation $-\alpha = \hbar eH/m$ is the second critical field H_{c2} . This highest value is attained for $v_z = 0$ and $n = 0$. Therefore Abrikosov considered only state corresponded the lowest Landau level $n = 0$ and without any gradient along magnetic field $\nabla_z\Psi = 0$.

Developing of this work Abrikosov has obtained in 1957 the famous solution of the GL equations according to which the mixed state of type II superconductor is a periodical vortex structure [1]. He treated the regime with

magnetic field H only slightly less than H_{c2} , where the solution of the complete GL equations (2) must have strong similarity to a certain solution of the linear equation (2). The equation (2) has many degenerate eigenvalues having the form

$$\Psi_\kappa = \exp i\kappa y \exp[-\frac{1}{2}(\frac{x - x_0}{\xi(T)})^2] \quad (5)$$

for $A_x = A_z = 0$ and $A_y = H_{c2}x$. Where $x_0 = \hbar\kappa/2eH_{c2}$ and κ is an arbitrary parameter. A general solution must be a linear combination of the Ψ_κ . Abrikosov was interested in a solution which is periodic both in x- and y-direction. Periodicity in y-direction is achieved by setting $\kappa = \kappa_k = 2\pi k/l_y$ yielding the period l_y , where k is a integer number. In this case the general solution will have the form

$$\Psi = \sum_k C_k \exp iky \exp[-\frac{1}{2}(\frac{x - x_k}{\xi(T)})^2] \quad (6)$$

Periodicity in x-direction can be established, if the coefficients C_k are periodic functions of k , such that $C_{k+l} = C_k$, where l is some integer. The particular choice of l determines the type of periodic lattice structure: at $l = 1$ - square lattice, at $l = 2$ - triangular lattice. The periodicity in x-direction $l_x = \hbar 2\pi/l_y 2eH_{c2}$ yields $l_x l_y H_{c2} = \Phi_0$, i.e., each unit cell of the periodic array contains one flux quantum.

Thus, Abrikosov has found a periodic lattice structure since he searched it. It is impossible to obtain any other result besides a periodical structure for the case of homogeneous, symmetric, infinite space. The long-range order of superconducting state is phase coherence. Because of it superconductor has zero resistance, the Meissner effect is observed and other macroscopic quantum phenomena take place. The famous Abrikosov result [1] states that an additional long-range order can exist in type-II superconductor. Can this statement be correct? Two long-range order in an one state it is too many, the more so, as single phase transition should be on the way from the normal to the Abrikosov state according to [1]. Non-zero density of superconducting pairs $n_s > 0$, the long-range phase coherence and the crystalline long-range order of vortex lattice appear simultaneously at $H = H_{c2}$ according to [1] obtained in the mean field approximation. It is assumed that second order phase transition takes place at H_{c2} as well as at T_c . Therefore it would be natural to think that long-range phase coherence appears at H_{c2} as well as at T_c . Nevertheless other long-range order - the vortex lattice engrossed attention of all scientists during posterior forty years. The scientists were deluded because of some motives but the main was the direct observations of the Abrikosov state. First of all because of it the concept of vortex lattice melting appeared and became very popular.

2.5. Experimental corroboration of the Abrikosov prediction.

FIG. 1: The flux-line lattice observed at the surface of a type II superconductor in an electron microscopy after decoration with Fe micro-particles. A remanent magnetic field of $H = 0.007$ T yields a flux-line spacing $a = (2\Phi_0/3^{1/2}H)^{1/2} \approx 580$ nm.

First experimental corroboration of the periodic magnetic flux structure predicted by Abrikosov was obtained by Cribier et al. in 1964 [22]. They investigated neutron diffraction through the interaction of the magnetic moment of the neutron with the magnetic field gradients in the mixed state and has found a periodic magnetic flux structure with triangular but no square symmetry predicted in the famous Abrikosov work [1]. The latter discrepancy was explained in the same year [2]. According to the mean field approximation a real state should correspond a minimum value of the GL free-energy. Abrikosov searched periodic structure corresponds this minimum and has found that it is a square lattice. Kleiner, Roth and Autler [2] had shown that a triangular periodic lattice structure corresponds a lower value of the GL free-energy.

The most direct proof of the triangular vortex structure of the mixed state has been obtained from experiments by Essmann and Trauble [23] utilizing a Bitter method in conjunction with electron microscopy. In such an experiment the magnetic flux structure is decorated using small magnetic particles and subsequently observed with some optical technique. The microscopic vortex structure in the mixed state and the magnetic field distribution have been investigated from the decoration, neutron diffraction [24-26] and other methods [27-29]. A great number of vortex structure images with and without crystalline order was obtained by many authors (see at Fig.1 a typical picture obtained by the Bitter method). Not only the vortex lattice but even its defects were observed with help of the method by Essmann and Trauble [21]. Such seeming corroboration of the prediction [2] obtained in the mean field approximation caught imagination although not only triangular vortex structure was observed.

The numerous experimental investigations of high quality samples with weak disorders have shown that dominant feature of the mixed state is the existence of the triangular vortex structure corresponding to the minimum of the GL free-energy. But it is important that because of the interaction between the vortex lattice and the crystal lattice of the superconductor, the orientation of the vortex lattice can be correlated with the orientation of the crystal lattice [21]. Departure from the triangular lattice structure can occur sometimes in the form of deviation from triangular symmetry [21,30]. The deviation from the triangular lattice structure are associated with the interaction between the vortex structure and the crystal lattice of the superconductor. This interaction can induce a transformation from triangular to square symmetry [31-33].

2.6. Absence of the crystalline long-range order of vortices in any real sample. The Larkin's result.

An important result obtained by Larkin in 1970 [34] shows that the crystalline long-rang order of the vortex lattice is unstable against the introduction of random pinning disorder. This result means that crystalline long rang order of vortex lattice is absent in any real superconductor having pinning disorders and the numerous direct observations demonstrate the crystalline order of vortex lattice in sample with enough weak pinning can not prove its existence. The Larkin's result raises a question: "Can the crystalline order observed in the vortex structure be spontaneous or it is determined by asymmetry (pinning disorders for example) of space?". The numerous observations of the deviation from the triangular lattice structure because of the interaction between the vortex structure and the crystal lattice and because of pinning disorders show that the vortex structure is rather like to a fishing net stretched with help of stakes than to a spontaneous vortex lattice. There is an important question: "What can be in the ideal case isotropic infinite space without disorder, i.e. when stakes are taken away?" An answer on this question is possible only in limits of fluctuation theory since the mean field approximation is not valid just in the ideal case considered by Abrikosov.

2.7. Invalidity of the Abrikosov solution for the ideal case. The result by Maki and Takayama.

Most physicists have got accustomed to assume that thermal fluctuations give only slight corrections to a result obtained in the mean field approximation. But it is not so in the case of the Abrikosov state. Taking into account of thermal fluctuations changes in essence the habitual notion about the mixed state of type II superconductor built because of the Abrikosov result. One of the qualitative changes in this notion connects with the invalidity of the Abrikosov solution just in the ideal case for which it was obtained. It is evidence from the calculation of fluctuation correction in the mixed state.

First an effective method of the calculation of the fluctuation correction to the Abrikosov solution was pro-

FIG. 2: Two triangular vortex lattice shifted on a vector λ .

posed by Eilenberger [35]. He took the function $\varphi_0(r)$ describing the triangular vortex lattice found in [2], shifted this function by a vector $\lambda = (\lambda_x, \lambda_y)$ in the x-y plane perpendicular to the magnetic field and multiplied it by $\exp(i2\pi\lambda_y x H/\Phi_0)$ to take care of the vector potential. The new function $\varphi_\lambda(r)$ describes also the triangular vortex lattice shifted on the vector λ , $|\varphi_\lambda(r)|^2 = |\varphi_0(r+\lambda)|^2$, Fig.2. An set of functions $\varphi_\lambda(r)$, where $\lambda_x = (l_x^2/L_y)k_x$; $\lambda_y = (l_y^2/L_x)k_y$ is orthogonal and spans the complete function subspace corresponded the lowest Landau level of a superconductor with sizes $L_x \times L_y$ across magnetic field. Here l_x and l_y are periods of the vortex lattice; k_x , k_y are nteger numbers.

It is important that all triangular vortex structure described by $\varphi_\lambda(r)$ have the same value of the GL free-energy. This means that the vortex lattice is absolutely unstable just in the ideal case considered by Abrikosov. All functions $\varphi_\lambda(r)$ should make the same contribution to the thermodynamic average $\langle |\Psi|^2 \rangle$ since they are equal in rights in the homogeneous, symmetric, infinite space. But the Abrikosov state can be stabilized by pinning disorders, asymmetry of space (because of asymmetry of the crystal lattice of the superconductor) and finite sizes $L_x \times L_y$ of superconductor. Therefore it is important to calculate the fluctuation corrections to the solution [2] obtained in the mean field approximation for superconductor with sizes $L_x \times L_y$.

The dependence of the fluctuation corrections $\Delta n_{s,fl}$ on superconductor size $L_x = L_y = L$ across magnetic field direction was calculated in the linear approximation by Maki and Takayama in 1971 [36]. Using the method proposed by Eilenberger [35] Maki and Takayama [36] have shown that the fluctuation correction $\Delta n_{s,fl}$ calculated in the linear approximation for a homogeneous, symmetric superconductor with sizes L is proportional $\ln(L/\xi)$ in three-dimensional case and $(L/\xi)^2$ in two-dimensional one. ξ is the coherence length of the superconductor. This result confirms the obvious conclusion

made above that the Abrikosov state should be absolutely unstable in a homogeneous, symmetric, infinite superconductor.

Nevertheless the Maki-Takayama result [36] seemed very queer for most scientists, because they think that it contradicts to the direct observations of the Abrikosov state. Almost nobody has believed in a reality of the Maki-Takayama result, even author. Maki (with Thompson) attempted to correct this result in [37]. But this work [37] by Maki and Thompson has an important mistake and therefore it can not be considered as a correction of the Maki-Takayama result. Only because of this mistake the fluctuation correction $\Delta n_{s,fl}$ calculated in [37] is finite for infinite superconductor. The Maki-Takayama result [36] is confirmed in the theoretical works [38-44].

It is important to emphasize that there is no real contradiction between the Maki-Takayama result [36] and the direct observation of the Abrikosov state. Moreover experimental results [45,46] corroborate the inapplicability of the Abrikosov theory in the regions where the Maki-Takayama theory predicts this inapplicability. One should take into account that in superconductor with real sizes L this inapplicability can become apparent in a wide region below H_{c2} only in two-dimensional superconductor (for example in thin film) where $\Delta n_{s,fl}$ is proportional $(L/\xi)^2$. In three-dimensional, i.e. bulk, superconductor, where $\Delta n_{s,fl}$ is proportional $\ln(L/\xi)$, the fluctuation correction to n_s exceeds the one calculated in the mean field approximation only in a narrow region near H_{c2} for all real L values. One should also take into account that pinning disorders can stabilize the Abrikosov state. Therefore only experimental results obtained at investigations of samples without or with enough weak pinning disorders can be used for verification of the Maki-Takayama result [36].

Such results corroborate qualitative difference between three- and two-dimensional superconductors [45,46]. In conventional bulk superconductor with weak pinning the transition into the Abrikosov state is only slightly lower the second critical field [45] whereas in thin film of like superconductor this transition is not observed down to very low magnetic field, much lower than H_{c2} [46]. This difference between three- and two-dimensional superconductors, observed also at investigation of high-Tc superconductors, corresponds to the Maki-Takayama result [36].

We can conclude from the comparison of the experimental result and the Maki-Takayama theory that the thermal fluctuation destroy the Abrikosov state almost in all region below H_{c2} in thin film with weak pinning and only a very narrow region near H_{c2} in bulk superconductor with any real and even unreal sizes. This can be explained by the great difference between the $(L/\xi)^2$ and $\ln(L/\xi)$ values. For example, for a real samples with $L = 1 \text{ mm}$ and $\xi = 10^5 \text{ mm}$, $(L/\xi)^2 = 10^{10}$ and therefore the Abrikosov solution is not valid almost in all mixed state region in thin film whereas $\ln(L/\xi) = 11.5$ and therefore it is not valid only in a narrow region near H_{c2} . It could be noted that width of this re-

gion increases only in 2 time in sample with unreal size $L = 10^5 \text{ mm} = 100 \text{ m}$. But it is important that $\ln(L/\xi)$ is infinite in the thermodynamic limit. This means that the numerous corroboration of the Abrikosov solution is only outward appearances since the experiment and theory deal with different matters. Although it is obvious that the Abrikosov state exists, this does not prove that the Abrikosov solution is valid in the ideal case of a boundless superconductor for which it was obtained. Together with the Larkin's result [34] this inapplicability means that neither the direct observation [21-33] nor the Abrikosov solution [1] are not evidence of spontaneous crystalline long-range order of the vortex lattice.

According to the mean field approximation the triangular vortex lattice [2] should be in the ideal case isotropic infinite space and two long-range orders exist in the Abrikosov state. But according to the fluctuation theory this approximation is not valid in the thermodynamic limit, i.e. just in this ideal case. The mean field approximation is valid if the fluctuation correction is small. But the theory shows that the value of this correction calculated in the linear approximation depends on superconductor sizes and is infinite for the infinite sizes. The later does not mean that the fluctuations are indeed infinite but it means that the mean field approximation, i.e. the Abrikosov solution, is not valid in the ideal case of a boundless superconductor without pinning disorder.

2.8. Absence of the second order phase transition at the second critical field.

Other qualitative change because of consideration of thermal fluctuations connects with the phase transition from the normal to the Abrikosov state. It was assumed during a long time [47-49] that a second-order phase transition between these states occurs at H_{c2} . This assumption was based on the observation of the specific-heat jump at H_{c2} which should be at the second-order phase transition in accordance with the theoretical result obtained in the mean field approximation. But it is not correct to conclude only on base the mean field approximation and the specific-heat jump about the availability of the phase transition. The mean field approximation disregards the sample dimensionality and the specific-heat jump can be observed in sample with any dimensionality whereas the second order phase transition is possible only in three-dimensional case [50]. Therefore it is important that the effective dimensionality of superconductor decreases on two near H_{c2} because of the Landau quantization. The thermodynamic peculiarity characteristic of second order phase transitions is in dependencies calculated for one-dimensional superconductor only in linear approximation and it is remove already in the Hartree approximation [50].

The reduction of the effective dimensionality is obvious in the linear approximation of the fluctuation theory. It was noticed first by Lee and Shenoy in the paper "Effective Dimensionality Change of Fluctuations in Superconductors in a Magnetic Field" [3]. The dimensionality

FIG. 3: The temperature dependence of excess conductivity $\Delta\sigma = \sigma - \sigma_n$ of single-crystal V_3Ge ($H_{c2}(0) = 14.7 \text{ T}$) in parallel magnetic field $h = H/H_{c2}(0) = 0.075$ obtained in [51]. The lines show theoretical dependencies for the paraconductivity calculated in [52]: the contribution of the Aslamasov-Larkin type σ_{AL} and the total with the one of the Maki - Thompson type, $\sigma_{AL} + \sigma_1$ and $\sigma_{AL} + \sigma_1 + \sigma_2$. $\epsilon_t = T/T_{c2} - 1$; $\sigma_0 = \pi e^2 / 2^{3/2} \hbar \xi(0) = 560 (\Omega \text{ cm})^{-1}$; $\sigma_0 / \sigma_n = 0.034$.

of fluctuations above T_c is determined by value of three superconductor dimensions, L_x, L_y, L_z , relatively the coherence length $\xi(T) = \hbar / (2m\alpha)^{1/2}$. Any gradient, for example $\partial\Psi/\partial x$, gives large contribution to the GL free-energy

$$f_{GL} = \alpha(T) [|\Psi|^2 + \frac{\beta}{2\alpha(T)} |\Psi|^4 + \xi^2(T) |(\frac{\partial}{\partial x} + \frac{\partial}{\partial y} + \frac{\partial}{\partial z})\Psi|^2] \quad (7)$$

at $L_x < \xi(T)$, $\xi^2(T) |\partial\Psi/\partial x|^2 > (\xi(T)/L_x)^2 |\Psi|^2 > |\Psi|^2$. Therefore the approximation $|\Psi|^2 = \text{constant}$ along x is admissible and $(\partial/\partial x + \partial/\partial y + \partial/\partial z)$ can be replaced by $(\partial/\partial y + \partial/\partial z)$ in the two-dimensional case. In a one-dimensional superconductor, with $L_x, L_y < \xi(T)$, $(\partial/\partial x + \partial/\partial y + \partial/\partial z)$ can be replaced by $\partial/\partial z$. In a bulk superconductor the gradient $(\partial/\partial x + \partial/\partial y)$ vanish near H_{c2} because of the Landau quantization. Therefore values of the fluctuation specific heat C [3], paraconductivity (i.e. excess conductivity because of superconducting fluctuations) along magnetic field $\Delta\sigma_{||}$ and others of bulk superconductor are proportional $(H/H_{c2} - 1)^{-3/2}$ in the linear approximation region above H_{c2} as in one-dimensional, where $C, \Delta\sigma_{||} \propto (T/T_c - 1)^{-3/2}$ but not as in three-dimensional superconductor, where $C, \Delta\sigma_{||} \propto (T/T_c - 1)^{-1/2}$. The $(H/H_{c2} - 1)^{-3/2}$ or $(T/T_{c2} - 1)^{-3/2}$ dependence in the linear approximation region near H_{c2} is corroborate by experimental data [51] and exact theoretical calculation [52]. For example, one can see from

FIG. 4: Dependencies of the normalized heat capacity $\Delta C_{exp}(T, H)/\Delta C_{MFT}$ on the reduced temperature $\Delta T = T - T_{c2}$ of a very pure niobium crystal at different values of magnetic field measured in [7]. ΔC_{exp} and ΔC_{MFT} (the specific-heat discontinuity expected from mean-field theory) are defined in the inset. A reduced temperature scale in units of $\delta = T(2e/\hbar)(k_B H/8\pi\Delta C)^{2/3}|TdH_{c2}/dT|^{1/3}$ is used in accordance of the scaling law proposed by Thouless [6]. The dashed curve is the temperature dependence expected for an ideal one-dimensional superconductor.

the data presented on Fig.3 that both the theoretical and experimental (in the linear approximation region $T/T_{c2} - 1 > 0.005$) of paraconductivity are close to $(T/T_{c2} - 1)^{-3/2}$.

The fluctuation values C , $\Delta\sigma_{||}$ and other calculated in the linear approximation diverge at $T = T_c$ both in three- and one-dimensional superconductors. But taking into account fluctuation interaction removes the divergence in one-dimensional case but it remains in three-dimensional superconductor. The divergence is removed already in the Hartree approximation, first approximation taking into account fluctuation interaction, in one-dimensional superconductor whereas it remains in three-dimensional case even in the exact solution. Because of the latter the λ anomaly should be observed on the of specific heat dependence for three-dimensional superconductor at $T = T_c$.

This λ anomaly of the specific heat dependence is main experimental evidence of the second order phase transition. But all experimental investigations show that the λ anomaly is absent at H_{c2} and the specific-heat “jump” at H_{c2} is described very well by theoretical dependence for one-dimensional model. Comparison of the experimental dependence of the specific-heat near H_{c2} with the theoretical one obtained in the Hartree approximation was made first in 1973 [4]. Bray has shown that the theoretical dependence calculated in the Hartree-Fock approximation with screened potential [5] describe better experimental data. It is important that thermodynamic values can be calculated exactly [53] for one-dimensional superconductor. The temperature dependencies of the fluctuation specific-heat of a pure niobium crystal measured at different value of magnetic field in [7] are obeyed

the scaling law valid in the lowest Landau level approximation and are described very well by the exact theoretical dependence [6] for a one-dimensional superconductor, Fig.4. All measurements of the specific heat show that a λ anomaly characteristic of second order phase transitions is not observed at H_{c2} . The λ anomaly is absence since second order phase transitions can not be in any one-dimensional system.

2.9. The discovery of the lost transition into the Abrikosov state.

Thus, in contrast to the belief in the second order phase transition at H_{c2} the reduction of the effective dimensionality and the investigations made in the middle of 70 years prove the absence of this transition. On the other hand the direct observations of the Abrikosov vortices, i.e. singularities in the mixed state with long-range phase coherence, and many other results prove the presence the long-range phase coherence and consequently a phase transition should be somewhere below H_{c2} . This phase transition into the Abrikosov state lost in 70 years was discovered first at investigation of paraconductivity in bulk conventional superconductors [8].

A sharp qualitative change of the resistive properties was observed in [8] against a background of a smooth dependence of paraconductivity in perpendicular magnetic field Fig.5. The current-voltage curves become non-Ohmic, the resistance increases sharply and its value measured at enough low current becomes equal zero in a narrow region, much narrower than the “jump” of specific-heat at H_{c2} Fig.4. Above this sharp change the current-voltage curves are Ohmic and the smooth dependence of paraconductivity was described by a theoretical one obtained for a one-dimensional model both above and below H_{c2} Fig.5. The second critical field was determined in this work from investigation of paraconductivity in the region of applicability of the linear approximation above H_{c2} [45]. The resistive feature observed in [8] was interpreted as a phase transition from fluctuation one-dimensional state to the Abrikosov state. This interpretation is obvious since the resistance can be zero only in a state with long-range phase coherence and should be non-zero in any state without phase coherence.

It is important that the transition into the Abrikosov state is observed below H_{c2} . The difference of the position of this phase transition from H_{c2} is enough small in bulk conventional superconductors. It was discovered accidentally at a comparison of experimental and theoretical dependencies of paraconductivity in the linear approximation region [45]. The comparison of excess conductivity $\Delta\sigma(T, H) = \sigma(T, H) - \sigma_n$ of single-crystal V_3Ge measured above H_{c2} with dependencies calculated numerically on base of results of a theory by Ami-Maki [52] showed that perfect accordance of the experimental data with the theoretical dependence takes place only if the transition into the Abrikosov state occurs at $H \approx 0.98H_{c2}$. Then it was assumed first that the transition into the Abrikosov state takes place below the second

FIG. 5: Magnetic field dependence of the excess conductivity for different measuring currents: $\bullet$ - $j = 0.5$ A/cm², $\times$ - $j = 2$ A/cm², $\circ$ - $j = 10$ A/cm². The line is the theoretical dependence for paraconductivity obtained in the Hartree approximation. The resistive transition shown at the bottom was measured at $j = 0.05$ A/cm² [8].

FIG. 6: Comparison of experimental and theoretical dependencies for paraconductivity in the linear approximation region at different values of the second critical field made in [45]: $\bullet$ - H_{c2} corresponds to the position of the resistive transition; $\circ$ - with the value of shifted $0.02H_{c2}$ upwards. The excess conductivity $\Delta\sigma = \sigma - \sigma_n$ was measured on single-crystal V_3Ge ($T_c = 6.1$ K) in perpendicular magnetic field at $T = 4.2$ K. $\epsilon_H = H/H_{c2} - 1$. The lines show theoretical dependencies calculated on the base of the Ami-Maki theory [52]: solid line - $\sigma_{AL} + \sigma_{MT}$; dashed - σ_{AL} .

critical field.

The second critical field was determined as a rule by the position of the resistive transition. But this method has not any theoretical ground in contrast to the comparison of paraconductivity dependencies used in [45]. Because of the absence of any transition at H_{c2} only method of the H_{c2} determination, which can be grounded theoretically in the framework of the mean field approximation, is magnetization measurement.

According to the mean field approximation the magneti-

FIG. 7: Dependencies of the critical current density j_c , of the voltage u/u_n and of the magnetization M on the relative magnetic $\epsilon_H = H/H_{c2} - 1$ at $T = 4.2$ K. a - for $Nb_{94.3}Mo_{5.7}$, $T_c = 7.5$ K, $H_{c2}(4.2) = 4.03$ kOe, the parameter of the GL theory $\kappa = 3$, u/u_n was measured at $j = 7$ A/cm²; b - for V_3Ge , $T_c = 6.1$ K, $H_{c2}(4.2) = 26.4$ kOe, $\kappa = 13$, u/u_n was measured at j from 0.1 to 1 A/cm². Curve 1 - $M(H)$ measured without a screening container, 2 - with the container. To the right, below a real part of the dynamic susceptibility is shown

zation of type II superconductor - $M \propto (H_{c2} - H)$ at $H_{c2}/3 < H < H_{c2}$ and $-M = 0$ at $H > H_{c2}$. The fracture of the $-M(H)$ dependence at H_{c2} becomes smooth because of fluctuation. But the linear dependence $-M \propto (H_{c2} - H)$ observed in a wide region allows to determine H_{c2} from the crossing of the linear dependencies $-M(H)$ above and below H_{c2} . The simultaneous measurements of the magnetization and resistive properties in [54] have confirmed the difference of the position of the transition into the Abrikosov state in V_3Ge found in [45] and this difference was determined in a superconductor $Nb_{94.3}Mo_{5.7}$ with other parameters Fig.7. It was found [45] that the appearance of a critical current, resistive transition and other features connected with the phase coherence are observed below H_{c2} , Fig.7. It is difficult to determine exactly the field H_{cr} of phase coherence appearance but it is important that $H_{cr} < H_{c2}$ both for V_3Ge and for $Nb_{94.3}Mo_{5.7}$ and that the $(H_{c2} - H_{cr})$ values differ for this superconductors: at $T = 4.2$ K, $H_{c2} - H_{cr} = 300 \div 600$ Oe for V_3Ge (at $H_{c2} \approx 26$ kOe) and $H_{c2} - H_{cr} = 10 \div 30$ Oe for $Nb_{94.3}Mo_{5.7}$ (at $H_{c2} \approx 4$ kOe) [45].

First attempt to explain the difference of the position of the transition into the Abrikosov state was made in 1990 [9]. The homogeneous, symmetric, infinite space was considered as well as in the Abrikosov work. It was shown that if the transition into the Abrikosov state exists in this ideal case it should be below H_{c2} because of thermal fluctuations. The position of this transition was denoted H_{c4} . The difference of the $(H_{c2} - H_{c4})/H_{c2}$ values observed in V_3Ge and $Nb_{94.3}Mo_{5.7}$ was explained in [9] by a scaling law obtained in the lowest Landau level

FIG. 8: The change of the phase diagram of type II superconductors in a magnetic field caused by the thermal fluctuation investigation. On the left side the mean field phase diagram supposed before the fluctuation investigation is shown. On the right side the phase diagram to the results of fluctuation investigation of bulk conventional superconductor [51,54,55] is shown.

approximation. According to this scaling law the transition into the Abrikosov state should be at the same value $\epsilon_{c4} = Gi^{-1/3}(T/T_c)^{-2/3}(H_{c2} - H_{c4})/H_{c2}^{2/3}(T)H_{c2}^{1/3}(0)$. Where Gi is the Ginzburg number; $H_{c2}(T) = H_{c2}(0)(1 - T/T_c)$; $H_{c2}(0) = -T_c(dH_{c2}/dT)_{T=T_c}$ is the GL second critical field at $T = 0$. The decreasing of the $(H_{c2} - H_{c4})$ difference near T_c following from the scaling law $(H_{c2} - H_{c4}) \propto H_{c2}^{2/3}(T) \propto (1 - T/T_c)^{2/3}$ corresponds to the experimental results [51,55]. The experimental investigations of fluctuation influence on the transition into the Abrikosov state in conventional bulk superconductors have allowed to alter the phase diagram of type II superconductor in a magnetic field, Fig.8.

2.10. The expansion of attention to fluctuation phenomena in the mixed state after the discovery of the high- T_c superconductors. The concept of vortex lattice melting.

The problem of fluctuation phenomena in the mixed state of type II superconductors became very popular soon after the discovery of high- T_c superconductors (HTSC) in 1986 since these phenomena are very appreciable in these superconductors with very small coherence length. Many new scientists enlisted the investigation of superconductivity because of the HTSC discovery. Most of them did not know about the results of the specific-heat investigations [4-7] refuting the assumption on the second order phase transition at H_{c2} and their knowledge was limited by the old notions from the [21,47-49] and other books. Therefore it was strange for them that the resistance of HTSC does not fall down to zero just below H_{c2} but decreases smoothly in a wide region. The result [8] shown on Fig.5 was little known. Therefore when this sharp change, called in some paper [10-12,56] resistive kink, was observed in $YBa_2Cu_3O_{7-x}$, Fig.9, it was misapprehended as a new result observed only in HTSC. But this result could be foreseen from the observations [8] and the scaling law. The comparison shows that there is only quantitative but not qualitative difference between $YBa_2Cu_3O_{7-x}$ and bulk conventional superconductors.

FIG. 9: Resistive transition in perpendicular magnetic fields of 0, 1, 2, 3, 4, 5, 6, 7 and 8 T for $H \parallel$ (a,b) of an untwinned $YBa_2Cu_3O_{7-x}$, crystal obtained in [12]. Inset: Phase diagram of the transition into the Abrikosov state.

The difference of the “kink” position from H_{c2} observed in $YBa_2Cu_3O_{7-x}$ corresponds to the same value ϵ_{c4} which was observed in V_3Ge and $Nb_{94.3}Mo_{5.7}$ [57]. Therefore I will designate the position of the “kink” H_{c4} .

The resistive kink was observed first only in four years after the HTSC discovery, in the beginning of the nineties, since this sharp change of resistive properties can be observed only in high quality samples, enough homogeneous and with weak pinning disorders. It will be explained below why the transition into the Abrikosov state can be narrow only at weak pinning disorders and why it is wide in most samples. The resistive kink observed in $YBa_2Cu_3O_{7-x}$ was interpreted as vortex lattice melting [10-12]. This interpretation became very popular [58-62] because most scientists did not understand enough clear that the transition into the Abrikosov state is not observed at H_{c2} . If anyone thinks that the transition into the Abrikosov state occurs at H_{c2} and this state is vortex lattice then he can interpret other transition observed below H_{c2} as vortex lattice melting. Now some experts understand that no transition is at H_{c2} . Moreover some of them understand that two long range order were predicted by Abrikosov. Then, vortex lattice melting is a transition from the Abrikosov state in the normal state (exactly in a fluctuation mixed state without phase coherence) and vortex liquid is a state without vortices. This interpretation could coincide with the one proposed in 1981 [8] if the Abrikosov state is vortex lattice with long-range phase coherence. Then two long-range orders disappear at H_{c4} .

This interpretation follows directly from habitual determination of phase coherence used by all theorists. When a theorist determines phase coherence as a coherence between two points $\langle \varphi(r)\varphi(r+r') \rangle$ he should conclude that long-range phase coherence should disappear in the Abrikosov state at any disappearance of crystalline long-range order of vortex lattice. According to this habit-

ual determination long-rang phase coherence is absent in the Abrikosov state observed in any real sample because pinning disorders destroy crystalline long-rang order of vortex lattice [34]. But why could zero resistance be observed in the real Abrikosov state if phase coherence is absent? This contradiction shows clear that the habitual determination of phase coherence is not valid for multi-connected superconducting state, such as the Abrikosov state.

The Abrikosov vortices appear since a magnetic flux can not penetrate inside superconductor with long-phase coherence and without singularity (the Meissner effect). Therefore a existence of the vortices is already evidence of long-range phase coherence. The existence of long-rang phase coherence is obvious in any vortex state, solid or liquid, when $\oint_l d\mathbf{l} \nabla \varphi = 2\pi n$, where n is a number of the Abrikosov vortices inside the closed path l . This long-rang phase coherence exists at any distribution of vortices inside l and its existence does not connect with crystalline long-rang order. Therefore vortex lattice melting is not only poor name. It is error. Numerous theories of vortex lattice melting at which only crystalline long-rang order disappears whereas long-rang phase coherence remains. Therefore they describe a transition which is not observed whereas the transition observed both in conventional superconductors and HTSC is not described for the present. In order to describe it a new determination of phase coherence should be used.

Some experts understand that vortices can not exist in the “vortex liquid”. But vortex liquid without vortices it seems very strange for many scientists. Indeed it sounds strangely. Therefore it is better to call the state above H_{c4} as mixed state without phase coherence by contrast with the Abrikosov state which is the mixed state with long-rang phase coherence. Although phase coherence is absent the density of superconducting electrons n_s in this state does not differ strongly from the one in the Abrikosov state and it can be enough high as it takes place for example in two-dimensional superconductor at magnetic field much lower H_{c2} [46]. It should be emphasized that the appearance of the long-rang phase coherence, i.e. the transition into the Abrikosov state, is not connected directly with the n_s appearance and its value. The specific-heat jump [4,7] and the fracture of magnetization dependence [54] connected with the n_s appearance are observed at H_{c2} whereas the zero resistance connected with the long-rang phase coherence appears at $H_{c4} < H_{c2}$ [8,10-12].

2.11. Experimental evidence of first order nature of the transition in the Abrikosov state.

Numerous investigations of the fluctuation phenomena in the mixed state of HTSC repeat in the main the results obtained at investigations of these phenomena in LTSC. Only qualitatively new, trustworthy result obtained at investigations of HTSC is experimental evidence of first order phase transition. It was assumed in [8] that a narrow

FIG. 10: The magnetic flux $\Phi = n\Phi_0 \neq 0$ can be inside a superconductor if only a singularity exists inside it (a). If a singularity is absent $n = 0$ and Meissner effect takes place (b).

thermodynamic feature should be observed at the transition into the Abrikosov state. Measurements of magnetization [13] and specific heat [14,65] have shown that a jump of thermodynamic quantities is observed at this transition in samples with enough weak pinning disorders. As it will be shown below the appearance of the long-rang phase coherence should be first order phase transition in the ideal or enough quality samples.

3. Two long rang order predicted by Abrikosov's solution.

The famous Abrikosov solutions [1], as well as all following solutions [2] obtained in the mean field approximation for an ideal superconductor, predict two long-rang orders in the Abrikosov state: crystalline long-rang order of vortex lattice and long-rang phase coherence. First order is more visual but the second one is more evident.

3.1. Long rang phase coherence.

In order to understand why the existence of long-rang phase coherence is more evident than the existence of vortex lattice one should recollect the Meissner effect. This effect has very simple, mathematical explanation when the wave function $\Psi(r) = |\Psi| \exp(i\varphi)$ introduced in the GL theory is used. It is well known that an integral along any closed path l of gradient of a function equals zero $\oint_l d\mathbf{l} \nabla \varphi = 0$ if this function does not have singularities inside the closed path l . It is important that the gradient of phase of the wave function is proportional to the momentum of superconducting pairs $\hbar \nabla \varphi = p = mv + 2eA$. Where A is the vector potential; v is the velocity of the superconducting pairs. Therefore when $\oint_l d\mathbf{l} \nabla \varphi = 0$ then the magnetic flux $\Phi = \oint_l d\mathbf{l} A$ contained within the closed path l should be equal zero $\Phi = \oint_l d\mathbf{l} A = (\hbar/2e) \oint_l d\mathbf{l} \nabla \varphi - (m/2e) \oint_l d\mathbf{l} v = 0$ if the velocity circulation equals zero $\oint_l d\mathbf{l} v = 0$.

FIG. 11: The singularities in type-II superconductor are the Abrikosov vortices. The $n = \Phi/\Phi_0$ vortices exist both at inhomogeneous (a), when the distance $a \approx (\Phi_0/H)^{1/2}$ between the vortices exceeds the penetration depth, $a > \lambda_L$, and homogeneous (b), when $a \ll \lambda_L$, magnetic field.

Thus, magnetic flux can not penetrate in a superconducting state with long rang phase coherence and without singularities since superconductivity is a macroscopic quantum phenomenon. This effect may be considered as a particular case of the flux quantization. The phase φ of the wave function $\Psi(r) = |\Psi| \exp(i\varphi)$ of superconducting electrons can cohere all over the volume of a superconductor. The relation for the superconducting current $j_s = n_s 2ev$

$$\oint_l dl \lambda_L^2 j_s = \frac{\Phi_0}{2\pi} \oint_l dl \nabla \varphi - \Phi \quad (8)$$

is valid in the region where the phase coherence exists. $\Phi_0 = \pi\hbar/e$ is the flux quantum; n_s is the superconducting electron density; $\lambda_L = (mc/e^2 n_s)^{0.5}$ is the London penetration depth; l is a closed path of integration. If a singularity is absent, then $\oint_l dl \nabla \varphi = 0$ since the closed path of integration l can be tightened down to point if the wave function $\Psi(r) = |\Psi| \exp(i\varphi)$ does not have any singularities. In this case the relation (8) is the equation postulated by F. and H. London for the explanation of the Meissner effect (see [21,66]). The magnetic flux can not penetrate in this case inside a superconductor with long-rang phase coherence, Fig.10.

3.2. The Abrikosov vortex is singularity in the mixed state with long-range phase coherence.

But the magnetic flux can be inside a superconductor if the wave function $\Psi(r) = |\Psi| \exp(i\varphi)$ has singularities Fig.10. In this case the closed path of integration l can not be tightened down to point. Therefore in the relation $\oint_l dl \nabla \varphi = n 2\pi$, n can be any integer number and consequently $\Phi = n\Phi_0 \neq 0$ even at $j_s = 0$ according to (8).

The penetration of the magnetic field in the mixed state of type II superconductor can be explain by both Mendelssohn's and Abrikosov's model. In both case the magnetic flux penetrates because of singularities. The two main difference between these models is that in the first case singularities exist always and in the second case

they, i.e. the Abrikosov vortices, appear because of magnetic field. Thus, the Abrikosov vortices are singularity in the mixed state with long rang phase coherence and therefore vortex existence is evidence of phase coherence existence in any case.

The existence of the phase coherence does not depend on any order of the vortex distribution since the relation $\oint_l dl \nabla \varphi = n 2\pi$, where n is number of the Abrikosov vortices inside l , is valid at any distribution of vortices inside l . Therefore the crystalline long-rang order of vortex lattice is not necessary order for the Abrikosov state.

3.3. Crystalline long-rang order of vortex lattice.

This order was predicted in the Abrikosov work [1] since an ideal case was considered in this work. It is impossible to obtain any other result besides a periodical structure for the case of homogeneous, symmetric, infinite space. The search of the periodical structure corresponded to minimum of the GL free-energy (1) can be reduced to the search of a function Ψ corresponded to the lowest Landau level and smallest value of the Abrikosov's parameter $\beta_A = \langle |\Psi|^4 \rangle / \langle |\Psi|^2 \rangle^2$. The GL free-energy (1) can be written in the form

$$f_{GL} = \sum_k [\alpha + (n + 0.5) \frac{2e\hbar H}{mc} + \frac{\hbar^2 q_z^2}{2m}] |\Psi_k|^2 + \frac{\beta}{2} \sum_{k_i} V_{k_1 k_2 k_3 k_4} \Psi_{k_1}^* \Psi_{k_2}^* \Psi_{k_3} \Psi_{k_4} \quad (9)$$

when the wave function $\Psi(r)$ is expanded by the eigenfunctions $\varphi_k(r)$: $\Psi(r) = \sum_k \Psi_k \varphi_k(r)$ corresponded different Landau level. Here $k = (n, l, q)$; n is the number of the Landau level; l is the index of the Landau level functions; q is the longitudinal (along magnetic field) wavevector; $V_{k_1 k_2 k_3 k_4} = \int_V d^3 r \varphi_{k_1}^* \varphi_{k_2}^* \varphi_{k_3} \varphi_{k_4}$. At $H < H_{c2} = -\alpha mc / e\hbar$ the eigenvalues $\Psi_k = \Psi_{0,l,0}$ corresponded to the lowest Landau level $n = 0$ and $q = 0$ can give negative value of the GL free-energy. In order to find a solution corresponded to the minimum free-energy at $H_{c2}/3 < H < H_{c2}$ only the contribution from the lowest Landau level and $q = 0$ should be considered. There is not difference between tree and two-dimensional superconductors in the mean field approximation. The GL free-energy in the both case is

$$f_{GL} = \frac{e\hbar}{mc} (H - H_{c2}) \langle |\Psi|^2 \rangle + \frac{\beta \beta_A}{2} \langle |\Psi|^2 \rangle^2 \quad (10)$$

suitable for this case the superconducting state with the average density of superconducting pairs $\langle n_s \rangle = \langle |\Psi|^2 \rangle = V^{-1} \int_V d^3 r |\Psi(r)|^2 = \sum_l |\Psi_l|^2 = (e\hbar / m\beta \beta_A) (H_{c2} - H)$ and an smallest value of the Abrikosov's parameter $\beta_A = \langle |\Psi|^4 \rangle / \langle |\Psi|^2 \rangle^2$ is thermodynamically most stable. The smallest β_A value could be equal 1 if $\Psi(r)$ is any function. But for the functions $\Psi(r)$ corresponded to the lowest Landau level

the β_A value should exceed 1. Abrikosov found [1] that a periodical square structure gives the value $\beta_A \approx 1.18$. Later [2] it was shown that the triangular lattice yield the smaller value $\beta_A \approx 1.16$.

4. Delusions provoked by the direct observation of the Abrikosov state.

Magnetic flux structures at a low field was observed at first experimental corroboration of the Abrikosov prediction. Therefore the visualization of the Abrikosov state as periodic flux line structure is predominated up to now. This visualization used already during forty years has provoked some delusions and even no quite correct names. These delusions provoked in one's turn erroneous notion about the transition from the Abrikosov state to the normal state. Therefore they should be indicated here.

4.1. Abrikosov vortices are not magnetic flux lines.

It is important to emphasize first of all that the Abrikosov vortices are no magnetic flux lines but are singularities in the mixed state with phase coherence. Because of the Bohr quantization the momentum circulation of superconducting pair along any closed path around single vortex should be equal $2\pi\hbar$

$$\oint_l dp = \oint_l dl(mv + 2eA) = m \oint_l dlv + 2e\Phi = 2\pi\hbar \quad (11)$$

The value $\oint_l dp/2e$ was called fluxoid by F.London [66] and $2\pi\hbar/2e$ is the fluxoid quantum. The relation (11) describes completely the velocity v distribution around the vortex. Most direct observations of the Abrikosov state were made in a low magnetic field, when a distance between vortices exceeds the penetration length $a \gg \lambda$, contours l exist for which $\oint_l dlv = 0$ and $\Phi = \Phi_0$ and the gradient of magnetic field induced by the current $j_s = n_s 2ev$ is enough large. In this case the Abrikosov vortex seems a solenoid in which the current $j_s = n_s 2ev$ induces magnetic flux, Fig.11a. Therefore it is misapprehended as a flux line [21,47-49,59]. But the nature of the vortex can not change in the opposite limit $a \ll \lambda$ when the current $j_s = n_s 2ev$ induces only negligible flux and it is obvious that the magnetic flux is induced by an external magnet Fig.11b. This flux changes very slightly when the vortices disappear at the transition from the Abrikosov state. If the vortices are flux lines why can magnetic flux remains when the vortices disappear?

Therefore it is obvious that the Abrikosov vortices are singularities in the mixed state with phase coherence. These singularities allow the magnetic flux to penetrate into a superconductor with long-range phase coherence but do not create the magnetic flux. A singularity can not exist without a medium. Consequently the existence of the vortices is an evidence of the existence of the phase coherence.

It is important to understand that the Abrikosov vortex is not magnetic flux line since this incorrect conception provoked some other no quite correct concep-

FIG. 12: The vortex flow in closed (A) and unclosed (B) type II superconductors placed in a magnetic field under the influence of an applied electric current. The current with the same density j is induced by a difference of magnetic fields inside H_{in} and outside H_{ex} the closed loop the case A and by a dc power source in the case B. The value of the magnetic flux changes with a speed $n_{vor}\Phi_0 2\pi R v_{vor}$ inside the closed loop (A) and does not change inside the unclosed loop (B).

tion: about causes of non-zero and zero resistance in the Abrikosov state and first of all about the vortex lattice melting.

4.2. Flux flow resistance is not induced by flux flow.

It is written in all books devoted the mixed state of type II superconductor that non-zero voltage in the Abrikosov state is induced by a motion of magnetic flux structure [21,47-49,59]. The magnetic flux lines move (with a velocity v_{vor}) under the influence of an electric current (with a density j) when the Lorentz force $f_L = j \times H$ exceeds a pinning force f_p [21,49,67], i.e. when the applied current exceeds a critical current, $j > j_c = f_p/B$. The steady-state motion of the magnetic flux structure induced by the applied electric current causes the time-averaged macroscopic electric field following Faraday's law $E = -gradV = -(v_{vor} \times H)$ [21,49,67]. The forces regulating the flux motion satisfy the following equation

$$f_L - f_p = \eta v_{vor} \quad (12)$$

where ηv_{vor} is the damping force, η is the viscosity coefficient. According to this equation a potential difference along x , $dV/dx = (H^2/\eta)(j - j_c)$ when the magnetic field H is directed along z , the current j - along x and vortices move along y . The slope of the current-voltage characteristic at $j > j_c$ is called flux-flow resistivity $\rho_f = H^2/\eta$.

But it is enough easy to show that this wide-spread conception of the flux-flow resistivity is not correct. Two cases of the vortex flow under the influence of an applied electric current are shown on Fig.12. The same current density j is induced by a difference of the magnetic field values inside H_{in} and outside H_{ex} of a closed superconducting cylinder in the case A and by an external dc

power source in a unclosed cylinder in the case B. The vortices move with the same velocity $v_{vor} = (f_L - f_p)/\eta$ from the outside to the inside of the both cylinders. It is obvious that the magnetic flux flows in the case A and does not flow in the case B since its value changes in time inside the closed cylinder and does not change inside the unclosed one. But it is obvious also that a potential difference $V \neq 0$ can be observed only in the case B when the flux flow is absent and can not be observed in the case A when it takes place.

Thus, in the contrast to conception of the flux-flow resistivity the potential difference is observed when the flux flow is absent and is not observed when the magnetic flux flows. This seeming paradox can be solved if we take into account that the momentum (phase gradient of wave function) is not the gauge-invariant value because of the vector potential A . A gauge-invariant value, such as velocity of superconducting pairs should be considered in order to find the real cause of the potential difference observed in the Abrikosov state. It is obvious that the integral $\int_l dlv$ along a path between points a-b (see Fig.12, B) does not change when vortices shift on a period of the vortex lattice if the current density j is constant in time. The same is right also for a closed path l in the case A. The current density $j = (H_{ex} - H_{in})/w$ changes in time in this case. But this change at vortex shifting on one period $\Delta j = -\Delta H_{in}/w = 2\Phi_0/Rw$ is very small at a large radius R of the cylinder and therefore can be disregarded.

The constancy of the velocity in the case A is following from the relation for the momentum circulation (11) $m \oint_l dlv = 2\pi\hbar n - 2e\Phi$. It is important here that the integral of the vector potential along a closed path is the gauge-invariant value $\oint_l dlA = \Phi$. The momentum circulation changes on $2\pi\hbar$ and the integral of the phase gradient $\oint_l dl\nabla\varphi$ changes on 2π when an Abrikosov vortex crosses the closed path l . But in the same time the magnetic flux Φ inside l changes on Φ_0 . Therefore when n' vortices have crossed the closed path l the value $2\pi\hbar n - 2e\Phi$ has not changed since $2\pi\hbar n' - 2en'\Phi_0 = 0$. Consequently the velocity does not change in the case A since the magnetic flux flow compensates for the change of the phase difference $\oint_l dl\nabla\varphi$ because of the vortex motion.

In the case B the flux flow is absent. Therefore a potential difference V should compensate for the change of the phase difference. The voltage V and the velocity of the phase difference change $d\varphi/dt$ is connected by the Josephson relation $d\varphi/dt = 2eV/\hbar$ [68]. Since the phase difference $\Delta\varphi$ between two points changes by 2π when a vortex crosses a line connecting these points then $d\varphi/dt = v_{vor}n_{vor}2\pi$ along a length unit. Consequently, the macroscopic voltage along a length unit is equal to $E = -gradV = (\hbar/2e)d\varphi/dt = v_{vor}n_{vor}(\pi\hbar/e) = v_{vor}n_{vor}\Phi_0$. Where v_{vor} is the velocity of the vortex flow, n_{vor} is the density of the vortices.

This result coincides nominally with the one obtained by the Faraday's law $E = -v_{vor} \times H$, because $H =$

$n_{vor}\Phi_0$ in the Abrikosov state. Therefore, it became possible that the resistivity in the Abrikosov state is considered as a consequence of flux flow in all textbooks [21,47-49] and majority of papers, although it is obvious that the magnetic flux does not flow in a superconductors in this case. It is obvious also that the Lorentz force can not be the driving force on an Abrikosov vortex [69]. One should use the more correct notation "vortex flow resistivity" instead of "flux flow resistivity" since the latter is not quite correct notation. The vortex should consider as singularity moving of which induces a change of phase difference.

4.3. Long range phase coherence but no vortex pinning is main reason of zero resistance in the Abrikosov state.

Although the conception about the Abrikosov state as magnetic flux structure is not correct it allowed to describe many properties and features of the mixed state with long-rang phase coherence of type II superconductors. It was explained in the Section 4.2 that the incorrect conception of the flux flow resistivity described enough well resistive properties of the Abrikosov state since the result given by it does not differ in the main from the one given by the correct conception. The conception of the magnetic flux structure has made greatest progress in the description of vortex pinning [70]. First of all because of this progress it is very popular. There is not a difference between this conception and the correct conception until only the mixed state with long-rang phase coherence is considered. But there is a difference based on principle when the transition from the Abrikosov state is considered.

According to the conception of vortex pinning the resistance can be equal zero in the Abrikosov state since the pinning force prevents from the vortex flow [70]. The pinning force exists since superconductor disorders eliminate the homogeneity of the space in which the vortex structure exists. The pinning disorders are very important for the Abrikosov state. As it was shown in the Section 2.6 this state is absolutely unstable in homogeneous infinite space. Without pinning disorders (including superconductor boundaries) vortex structure should move under the influence of anyhow weak electric current. Therefore the vortex pinning is considered as the reason of non-dissipation current in the Abrikosov state. It is correct.

But one should remember at a consideration of the transition from the Abrikosov state that any non-dissipation current is observed in superconductors first of all because of long-range phase coherence. One should remember that the Abrikosov vortices are singularities in the mixed state with the long-rang phase coherence. Therefore the vortex pinning is also a consequence of the phase coherence. The vortex pinning can not exist in a state without the phase coherence. Therefore the transition between the mixed states with and without long-range phase coherence can be fixed first of all by the use of an observation of disappearance of the non-dissipation

current and the vortex pinning. Changes of the resistive properties should be observed first of all at the transition into the Abrikosov state, because a transition from the paraconductivity regime to the vortex flow regime must occur and the vortex pinning can appear at the appearance of the long-range phase coherence

4.4. Fundamental differences between vortex “lattice” and crystal lattice.

Many scientists consider the Abrikosov state as flux line lattice like an atom lattice, or a lattice of long molecules. Therefore it is important to emphasize that the Abrikosov state differs in the main on any crystalline lattice. One should once again say that the Abrikosov vortex is singularity but is not a flux line. The flux lines can be likened interacted particles which can form a lattice. Whereas singularities witness an other long-range order. The energy of vortices is inseparable from the energy of their interaction whereas the energy of atoms or molecules is much larger than the energy of their interaction. Therefore atoms and molecules remain almost invariable when their lattice melts. But it is impossible to say about the vortices. Therefore the popular image of flux line lattice misleads only and does not correspond to the facts.

All atom and molecule lattices are formed in homogeneous symmetric space only because of their mutual interaction. Just therefore the melting of these lattice is phase transition. The distinguishing feature of phase transition is spontaneous change of a symmetry [71]. Any change of a symmetry can be only spontaneous in any homogeneous symmetric space if any external influence does not break the symmetry. An external influence can make a change of a symmetry non-spontaneous and then the phase transition can disappear. Such disappearance takes place with the ferromagnetic transition in a strong magnetic field.

The vortex lattice predicted by Abrikosov breaks displacement symmetry. The same symmetry is broken by pinning disorders. Therefore the existence of pinning disorders is the external influence because of which the breach of displacement symmetry at the transition into the Abrikosov state can be non-spontaneous. It is important to remember that the real Abrikosov state is observed in an inhomogeneous space with broken displacement symmetry. Since the experimental results show strong influence of pinning disorders and symmetry of the crystal lattice of the superconductor on the vortex structure [21,31-33,72-76] it is important to answer on the question: “What state could be in homogeneous symmetric infinite space, i.e. in the space in which atom and molecule lattices exist?”

5. Qualitative change because of taking into account of thermal fluctuation.

Fluctuation theory does not limit oneself to the search of a state corresponded to minimum of the GL free-energy (1) but considers all possible states and calculates ther-

modynamic average of different quantities. The thermodynamic average of any quantity, for example order parameter, is

$$\langle |\Psi|^2 \rangle = \frac{\sum |\Psi|^2 \exp(-F_{GL}/k_B T)}{\sum \exp(-F_{GL}/k_B T)} \quad (13)$$

In this case the total relation (1) of the GL free-energy should be used. But near the second critical field H_{c2} this relation can be simplified since at $h = H/H_{c2}(T = 0) \gg (k_B T_c/H_c^2(0)\xi^3(0))^2$, $H - H_{c2}(T) \ll 2H$ above H_{c2} and $H > H_{c2}/3$ below H_{c2} the main contribution to any thermodynamic average gives functions corresponded to the lowest Landau level with $n = 0$. Main qualitative changes because of taking into account of thermal fluctuation are obvious in this lowest Landau level approximation. Therefore it will be considered first of all in this paper.

5.1. The lowest Landau level approximation.

The density of the GL free-energy in the lowest Landau level (LLL) approximation is

$$f_{GL} = \sum_k \left[\frac{e\hbar}{m} (H - H_{c2}) + \frac{\hbar^2 q_z^2}{2m} \right] |\Psi_k|^2 + \frac{\beta}{2} \sum_{k_i} V_{k_1 k_2 k_3 k_4} \Psi_{k_1}^* \Psi_{k_2}^* \Psi_{k_3} \Psi_{k_4} \quad (14)$$

where $\Psi_k = \Psi_{0,l,q}$. The summation by the longitudinal wave-vector $q = 2\pi l/L_z$ depends on a superconductor size L_z along magnetic field, where l is a integer number. In bulk sample the difference between values $\hbar^2 q^2/2m$ corresponded adjacent values of wave-vector is much lesser than the first addendum in (14) $\hbar^2 q^2(l+1)/2m - \hbar^2 q^2(l)/2m \approx (2\pi\hbar)^2/2mL_z^2 \ll (e\hbar/m)|H - H_{c2}| < (e\hbar/m)H_{c2} = (e\hbar/m)\Phi_0/2\pi\xi^2(T) = \hbar^2/2m\xi^2(T)$. Therefore the summation can be replaced by integration in tree-dimensional superconductor with $L_z \gg 2\pi\xi(T)$. In the opposed limit $L_z \ll 2\pi\xi(T)$ of two-dimensional superconductor the contribution to any thermodynamic average of the functions with $q = 0$ is much larger than the one of all other functions with $q > 0$. Therefore one can limit oneself to $q = 0$ in (14) in case of thin film and layered superconductor

$$f_{GL} = \frac{e\hbar}{mc} (H - H_{c2}) \sum_k |\Psi_k|^2 + \frac{\beta}{2} \sum_{k_i} V_{k_1 k_2 k_3 k_4} \Psi_{k_1}^* \Psi_{k_2}^* \Psi_{k_3} \Psi_{k_4} \quad (15)$$

where $\Psi_k = \Psi_{0,l,0} = \Psi_l$. This relation repeats the relation (10): $\sum_l |\Psi_l|^2 = \langle |\Psi|^2 \rangle$ and $\sum_l V_{l_1 l_2 l_3 l_4} \Psi_{l_1} \Psi_{l_2} \Psi_{l_3} \Psi_{l_4} = \langle |\Psi|^4 \rangle = \beta_A \langle |\Psi|^2 \rangle^2$. But it is very difficult to calculate thermodynamic average of the Abrikosov's parameter β_A and to find the

transition into the Abrikosov state taking into account of thermal fluctuation even for this simplest case. According to the mean field approximation the Abrikosov's parameter β_A can make sense only below H_{c2} since the density of superconducting pairs $\langle |\Psi|^2 \rangle = 0$ at $H > H_{c2}$. But because of fluctuations $\langle |\Psi|^2 \rangle > 0$ both below and above H_{c2} . According to fluctuation theory thermodynamic average of the Abrikosov's parameter $\langle \beta_a \rangle$ changes from $\langle \beta_a \rangle = 2$ in fluctuation region enough above H_{c2} to $\beta_A \approx 1.159595$, calculated for triangular structure [2], in the mixed state enough below H_{c2} (see for example [77]). The dependence $\langle \beta_a \rangle (H/H_{c2})$ was calculated for the present only in some approximations and only for two-dimensional superconductor [77, 44]. These results does not give an answer having a single meaning on existence of the Abrikosov state. Although a total solution about the transition into the Abrikosov state is not obtained for the present we can make some conclusions about its possible position considering the GL free-energy in the LLL approximation (14).

5.2. Reduction of the effective dimensionality near H_{c2} .

It is important that the GL free-energy of bulk superconductor in the LLL approximation (14) is like the one of one-dimensional superconductor. There is no difference between superconductors with different dimensionality according to the mean field approximation. Therefore it is assumed during a long time that the second law phase transition takes place at H_{c2} since the "jump" of the specific heat is observed at H_{c2} as well as at T_c . This "jump" $C_s - C_n = \alpha_0^2/\beta$ should be observed according to the mean field approximation. Therefore the observation only this "jump" is not evidence of the second order phase transition. This "jump" should be observed in superconductor with any dimensionality but the second order phase transition can be only in three-dimensional superconductor and λ anomaly of the specific heat dependence should be observed at this transition.

But the λ anomaly was not observed in superconductors for the present. It is not observed at T_c because the coherence length of superconductors is very large. Therefore the width of phase transition is very small and the λ anomaly can not be observed in a real experiment. It is assumed during a long time that the same takes place also at H_{c2} . Therefore the experimental results obtained in the seventieth years [4-7] are very important. They have shown that the dependence ("jump") of the specific heat of bulk superconductor near H_{c2} can be described by theoretical dependence for a one-dimensional superconductor and therefore the second order phase transition into the Abrikosov state can not be at H_{c2} .

The λ anomaly is observed because of a divergence of the coherence length $\xi(T)$ at the transition. The coherence function for bulk superconductor in a linear approximation region above T_c is $g(R) = \langle \Psi^*(r)\Psi(r+R) \rangle = (mk_B T / 2\pi\hbar^2) \exp[-R/\xi(T)]/R$ at $R \gg \xi(T)$ [49] and typical size of superconducting fluctuation drops above T_c equals $\xi(T)$.

FIG. 13: Superconducting drops above T_c and above H_{c2} . $D = \xi(T) = \xi(0)(T/T_c - 1)^{-1/2}$; $h = \xi_z = (\Phi_0/2\pi(H - H_{c2}))^{1/2}$; $d = \xi_\rho \approx (\Phi_0/H)1/2$

FIG. 14: Dependencies of excess conductivity $\Delta\sigma/\sigma_n = \sigma(T, H)/\sigma_n - 1$ of single-crystal V_3Ge on the value of parallel and perpendicular magnetic field at $T = 4.2$ K measured in [51]. $\epsilon_H = H/H_{c2} - 1$, $H_{c2} = 4.32$ T.

The fluctuation drop is spherical when magnetic field is absent: $R = (x^2 + y^2 + z^2)^{1/2}$, Fig.13 and its radius increases together with $\xi(T)$ at $T \rightarrow T_c$. The second low phase transition takes place when $\xi(T)$ (radius fluctuation drop) mounts to infinity (to sample size in real case) and phase coherence spreads out the whole of superconductor. According to the linear approximation of the fluctuation theory $\xi(T) = \xi(0)(T/T_c - 1)^{1/2}$ both in three- and one-dimensional superconductor. But already in the Hartree approximation, first approximation taking into account fluctuation interaction, qualitative difference is between three- and one-dimensional superconductor. Taking into account fluctuation interaction

FIG. 15: The magnetic field dependencies of potential difference measured on a branch V_1 (lower curve) and on a main part V_2 (upper curve) of a single crystal V_3Ge sample at constant current through the main part of the sample and $T = 4.2$ K [51,79]. The non-local resistance observed near H_{c2} may be interpreted as a consequence of the anisotropy of the conductivity, Fig.14, or superconducting drops, Fig.13.

removes the divergence of the coherence length in one-dimensional case but this divergence remains in three-dimensional superconductor. Therefore the second order phase transition and the λ anomaly of the specific heat take place at T_c in bulk superconductor and are absent in one-dimensional case.

The coherence function for bulk superconductor near H_{c2} is like to one for one-dimensional superconductor. The coherence length increases only along magnetic field at $H \rightarrow H_{c2}$. In the linear approximation $g(\rho, z) \propto \exp(-|z|/\xi_z) \exp(-\rho/\xi_\rho)$ [49], where $\xi_z = [\Phi_0/2\pi(H - H_{c2})]^{1/2}$ and $\xi_\rho = (2\Phi_0/\pi H)^{1/2}$ are the coherence lengths along and across magnetic field; $\rho = (x^2 + y^2)^{1/2}$. Size of superconducting drop along magnetic field ξ_z exceeds considerably the one across the H direction, $\xi_z \gg \xi_\rho$, near H_{c2} , at $|H - H_{c2}| \ll H$, Fig.13. It is manifested in the anisotropy of paraconductivity [78,79] along and across magnetic field observed near H_{c2} , Fig.14, and the non-local resistance, Fig.15. The anisotropy increases near H_{c2} , Fig.14, as well as the ξ_z/ξ_ρ relation. The ξ_z value increases at $H \rightarrow H_{c2}$ but remains finite not only at $H = H_{c2}$ but also $H < H_{c2}$, as well as the conductivity along magnetic field, Fig.15, since taking into account fluctuation interaction removes the divergence in one-dimensional case.

5.3. Scaling law.

Since the GL free-energy of whole superconductor $F_{GL} = V f_{GL}$ is used in the relations for thermodynamic average (13) it is more handy to replace of Ψ_k in the relation (14) for $V f_{GL}$ by $\Psi'_k = V^{1/2} \Psi_k$. Then

$$\frac{F_{GL}}{k_B T} = \sum_k \left[\frac{e\hbar}{mk_B T} (H - H_{c2}) + \frac{\hbar^2 q_z^2}{2m} \right] |\Psi'_k|^2 +$$

$$\frac{\beta}{2V k_B T} \sum_{k_i} V_{k_1 k_2 k_3 k_4} \Psi'^*_{k_1} \Psi'^*_{k_2} \Psi'_{k_3} \Psi'_{k_4} \quad (16)$$

It is handy to use a dimensionless unit system in which $(e\hbar H_{c2}(0)/mk_B T)^{1/2} G i_H^{1/2} \Psi'_k = \Psi''_k$, a length unit across magnetic field is $(\Phi_0/H)^{1/2}$ and a length unit along magnetic field is $\xi(0) G i_H$ [9,57], where $G i_H = G i^{1/3} (th)^{2/3}$ is the Ginzburg number in magnetic field; $G i = (k_B T_c / H_c^2(0) \xi^3(0))^2$ is the Ginzburg number; $t = T/T_c$; $h = H/H_{c2}(0)$; $H_{c2}(0)$ is the GL second critical field at $T = 0$. It is followed from (13) and the relation for the GL free-energy in the dimensionless unit system

$$\frac{F_{GL}}{k_B T} = \sum_k (\epsilon_n + q^2) |\Psi|^2 + \frac{1}{2V} \sum_{k_i} V_{k_1 k_2 k_3 k_4} \Psi^*_{k_1} \Psi^*_{k_2} \Psi_{k_3} \Psi_{k_4} \quad (17)$$

that thermodynamic average of all values is universal function of $\epsilon = (h - h_{c2})/G i_H = (h - h_{c2})(ht)^{-2/3} G i^{-1/3}$ in the LLL approximation.

In order to find the transition into the Abrikosov state the veritable free-energy

$$F = -k_B T \ln \sum_{\Psi_k} \exp\left(-\frac{F_{GL}}{k_B T}\right) \quad (18)$$

can be considered. Since the free-energy depends on only parameter ϵ all theories should give an identical dependence of a critical field H_{c4} position on temperature and on the Ginzburg number defined by the relation $\epsilon_{c4} = (h - h_{c2})(ht)^{-2/3} G i^{-1/3}$. This scaling law should be observed in the region $h \gg G i$, $h - h_{c2} \ll 2h$ and $h > h_{c2}/3$ where the LLL approximation is valid. This means that a coincidence of a theoretical dependence $H_{c4}(T, G i)$ with the experimental one does not prove correctness of the theory. This proves only that the LLL approximation is valid.

The relation (17) in the LLL approximation is close to the one for a one-dimensional superconductor. We may write this relation in following form

$$\frac{F_{GL}}{k_B T} = V(\epsilon \langle |\Psi|^2 \rangle + \frac{1}{V} \int_V dr^3 \Psi^* \frac{d^2}{dz^2} \Psi + \frac{\beta_a}{2} \langle |\Psi|^2 \rangle^2) \quad (19)$$

The main difference the relation (19) from the one for a one-dimensional superconductor consists in the generalized Abrikosov parameter value β_a which is determined by a distribution of the order parameter in the space. Much below the transition $\Psi(r) = \text{const}$ in one-dimensional superconductor and consequently $\beta_a = 1$. But function $\Psi(r) = \text{const}$ is not belong to the LLL functions. This has a simple interpretation: a magnetic field must penetrate through superconductor. Therefore $\langle \beta_a \rangle$ changes from 2 at $H \gg H_{c2}$ [77] to $\beta_A \approx 1.159595$ at $H \ll H_{c2}$ [2].

5.4. Density of superconducting pairs and phase coherence.

FIG. 16: Temperature dependencies of density of superconducting pairs in the dimensionless unit system calculated on the base of the GL free energy (19) in different approximations [51]: the solid straight line is the mean field approximation for bulk type II superconductor [1] near H_{c2} ; the dashed straight line is the same for a 1D superconductor; the solid curve is exact fluctuation theory for 1D superconductor [80]; the dot curve is Hartree-Fock approximation with screened potential [5]; the dash-dot curve is Hartree approximation; the dash curve is the linear approximation of the fluctuation theory.

FIG. 17: Dependence of the magnetization on the magnetic field in the fluctuation region near H_{c2} of a single-crystal $Nb_{94.3}Mo_{5.7}$ sample at $T = 4.2$ K [54]: wave curve is experimental dependence; dashed curve is linear approximation; dash-dot - Hartree-Fock approximation with screened potential; solid - mean field approximation.

Although the thermodynamic average of the Abrikosov parameter $\langle \beta_a \rangle$ is not calculated exactly for the present for the whole LLL approximation region the dependence of density of superconducting pairs $\langle n_s \rangle = \langle |\Psi|^2 \rangle$ can be calculated enough exactly from (19) since it is known that $2 > \langle \beta_a \rangle \geq 1.159595$. It is important that the appearance of phase coherence is connected rather with the $\langle \beta_a \rangle$ value than with $\langle n_s \rangle$.

According to the mean field approximation a non-zero density of superconducting pairs n_s and long-rang phase coherence appear simultaneously at $H = H_{c2}$. According

FIG. 18: The resistive transition of a single-crystal V_3Ge sample for different current densities for perpendicular and parallel magnetic field. The lines denote the theoretical dependencies obtained in the Hartree approximation for perpendicular (dashed) and parallel (solid) magnetic fields [51].

to the fluctuation theory $\langle n_s \rangle$ appears already above H_{c2} . Appearance of phase coherence loses a connection with the second critical field but the H_{c2} remains a particular point for the $n_s(H)$ dependence.

The theoretical dependencies of the thermodynamic average density of superconducting pairs $\langle |\Psi|^2 \rangle$ for one-dimensional superconductor and a bulk superconductor in the LLL approximation are compared on Fig.16. The dependence calculated in the Hartree-Fock approximation with screened potential [5] coincides almost completely with the one obtained by the exact solution for one-dimensional model [80]. The dependence obtained in the Hartree approximation differs from the exact one near the critical point. All three dependencies have the same asymptotic $\langle |\Psi|^2 \rangle = -\epsilon$ at $-\epsilon \gg 1$. It differs from the asymptotic for the LLL approximation $\langle |\Psi|^2 \rangle = -\epsilon/\beta_a$ at $-\epsilon \gg 1$ since for both one-dimensional superconductor and Hartree (Hartree-Fock) approximations $\beta_a = 1$ at $-\epsilon \gg 1$.

According to (18) and (19) the magnetization $M = -dF/dH$ is proportional to $\langle n_s \rangle$ and the specific heat $C = -T(d^2F/dT^2)$ is proportional to $T(d\langle n_s \rangle/dT)$ in the lowest Landau level approximation region. These and also some other values are determined first of all by average density of superconducting pairs and depend weakly from existence of phase coherence. Therefore the one-dimensional model is described enough well the specific heat Fig.4 and magnetization dependencies Fig.17 in the mixed states both without and with long-rang phase coherence. Dynamical properties, such as resistance, are described enough well by the one-dimensional model only in the mixed state without phase coherence, Fig.18. Sharp deviation of the experimental resistance dependencies from the theoretical one obtained in the one-dimensional model is observed at the transition into the Abrikosov state, Fig.18. This deviation is more appreciable for resistance dependence in perpendicular magnetic field because of high anisotropy of paraconductivity at

H_{c4} , Fig.18. The length of phase coherence changes first of all across magnetic field at the sharp transition into the Abrikosov state.

6. Transition into the Abrikosov state.

Thus, dependence near H_{c2} of the quantities connected with the average density of superconducting pairs, such as magnetization, specific-heat, paraconductivity, can be enough easy described in the LLL approximation. The same can be made for the resistance dependencies in the mixed state without phase coherence. The sharp deviation from the theoretical dependence should be interpreted as a consequence of the transition into the Abrikosov state. This interpretation is having one meaning since just such qualitative change of the resistive properties should be observed at the long-rang phase coherence appearance. The resistance can be equal zero because of the vortex pinning in the Abrikosov state, i.e. in the mixed state with long rang phase coherence, whereas in the fluctuation mixed state without long rang phase coherence it has a non-zero value.

The sharp qualitative change of the resistive properties is observed at $H_{c4} < H_{c2}$ in all high qualitative bulk superconductors with enough weak pinning disorders, both conventional [8] and HTSC [11,12,56]. The great difference of the $(H_{c2} - H_{c4})$ value for superconductors $Nb_{94,3}Mo_{5,7}$, V_3Ge and $YBa_2Cu_3O_{7-x}$ corresponds to the great difference of the Ginzburg number and $(H_{c2}(0))$ value [57]: $Nb_{94,3}Mo_{5,7}$ $Gi = 10^{-9}$, $H_{c2}(0) = 0.8$ T; V_3Ge , $Gi = 10^{-6}$, $H_{c2}(0) = 12$ T; $YBa_2Cu_3O_{7-x}$ $Gi = 10^{-2}$, $H_{c2}(0) = 200$ T. The same experimental value $\epsilon_{c4} \approx 1$ for these superconductors conforms the scaling law of the LLL approximation. Therefore there is a base to think that the experimental determination of the transition into the Abrikosov state in bulk superconductors with weak pinning disorders is enough reliable. But theoretical description of the phase coherence appearance is absent for the present. This problem is not solved completely up to now. Some theories, [9,81] and others including the vortex lattice melting theories, calculate the value $(1 - H_{c4}/H_{c2})$ enough close to the one observed experimentally in bulk superconductors, both conventional and $YBa_2Cu_3O_{7-x}$. But this coincidence does not mean that these theories describe indeed the transition into the Abrikosov state, since it may be only a consequence of the scaling law.

6.1. The phase transition into the Abrikosov state of an ideal superconductor must be first order.

Although the transition into the Abrikosov state is not described theoretically for the present we can conclude anything about it from consideration of difference between states with and without long rang phase coherence. We can show that it should be first order phase transition and should occurs below the second critical field.

The transition into the Abrikosov state can not be second order since size of superconducting drops increases only along magnetic field near H_{c2} , Fig.13. They

have approximately the same size across magnetic field $\xi_\rho = (2\Phi_0/\pi H)^{1/2}$ in all region near the second critical field, at $H \approx H_{c2}$. This size is much smaller than a size L of a real sample, $(2\Phi_0/\pi H)^{1/2} \ll L$. For example in work [8], the sharp transition was observed in a sample with $L \approx 1$ mm at $H_{c4} \approx 40$ kOe, what corresponds $\xi_\rho = (2\Phi_0/\pi H_{c4})^{1/2} \approx 2 \cdot 10^{-5}$ mm. The observation of the non-dissipation current below H_{c4} means that phase coherence spreads over whole superconductor with macroscopic sizes $L \gg (2\Phi_0/\pi H)^{1/2}$. If the sample is absolutely homogeneous only these two characteristic lengths L and $(2\Phi_0/\pi H)^{1/2}$ exist across magnetic field. Consequently phase coherence should appear by jump from $(2\Phi_0/\pi H)^{1/2}$ to L and the transition into the Abrikosov state should be first order in an ideal superconductor without disorders. Thus, the result obtained in the fluctuation theory differs qualitatively from the one obtained in the mean field approximation. The transition into the Abrikosov state can not be second order phase transition. It must be first order phase transition in ideal superconductors without disorder.

The size of superconducting drops across magnetic field $\xi_\rho = (2\Phi_0/\pi H)^{1/2}$ in the mixed state without phase coherence is approximately equal the distance between the vortices $(2\Phi_0/\sqrt{3}H)^{1/2}$ in the Abrikosov state. But these two mixed states have different topology. The Abrikosov state is multi-connected superconducting state. Therefore the definition of the phase coherence by the correlation function is unsuited for it. The phase difference

$$\varphi_1 - \varphi_2 = \int_l dl \nabla \varphi = \int_l dl p/\hbar = (m/\hbar) \int_l dl v + 2e \int_l dl A \quad (20)$$

is not a gauge-invariant value. But it is not main obstacle for the definition of phase coherence. Different gauge-invariant values, $(\varphi_1 - \varphi_2) - 2e \int_l dl A$ and others, were used in some papers for the definition of the phase coherence through the correlation function [39,47,82,83]. Different definitions of the phase of the gauge-invariant order parameter in the mixed state of type II superconductors are compared in [84,85]. These definitions give different result [84,85]. But it is main that all definitions of the phase through the correlation function are not valid for the Abrikosov state. Indeed, it is obvious that if the phase coherence is defined as any correlation between two points then long-rang phase coherence is absent in the Abrikosov state with a chaotic distribution of vortices, since any shift of a vortex alter in a point not only the phase, which is not a gauge-invariant value, but also gauge-invariant values, for example density of superconducting current. The chaotic distribution is observed in samples with strong pinning disorders in which the non-dissipation current (critical current) has highest value. Thus, there is obvious contradiction since the non-dissipation current is a consequence of long-range phase coherence. We should emphasize once again that existence of singularities (i.e. Abrikosov vortices) of the mixed state with long-rang phase coherence is evidence of long-rang phase coherence. Therefore it is natural to

define phase coherence through the relation

$$\oint_l dl \nabla \varphi = n 2\pi \quad (21)$$

where n is the number of the fluxoids inside a closed path l . The long-rang phase coherence exists if this relation makes sense and is correct for any closed path l which does not cross any non-superconducting region. This definition is valid for both the Meissner and Abrikosov states. It is valid for the Abrikosov state without depending on vortex distribution, for samples both without and with strong pinning disorders.

It is important that phase coherence appearance in these two opposite limits may be qualitatively different. It was shown above that length of phase coherence should change by jump and the transition into the Abrikosov state should be first order in an ideal superconductor in which only two characteristic lengths L and $(2\Phi_0/\pi H)^{1/2}$ exist across magnetic field. Pinning disorders give an additional characteristic length - distance between pinning centers d_p . In this case the length of phase coherence can jump from $(2\Phi_0/\pi H)^{1/2}$ to d_p . If $d_p \approx (2\Phi_0/\pi H)^{1/2}$ then the jump is absent. Strong pinning changes type of this transition. It has numerous experimental corroboration. The sharp transition into the Abrikosov state is observed only in samples with enough weak pinning disorders. In the overwhelming majority of samples this transition is smooth.

Because of the importance of pinning disorders for type of the transition in the Abrikosov state we will consider separately superconductor with weak and strong pinning disorders. There is also an important qualitative difference between three- and two-dimensional superconductors.

6.2. Transition into the Abrikosov state in bulk superconductors with weak pinning disorders.

The narrow transition into the Abrikosov state was found first only in 1981 since most samples of type II superconductors is not enough homogeneous and have strong pinning disorders. The samples have different width of the resistive transition because of heterogeneity and pinning disorders [51]. For example the width of the resistive transition in perpendicular magnetic field of different single-crystal and polycrystalline V_3Ge samples used in [45] was from 0.002 to 0.15 H_{c2} . The intrinsic (only because of thermal fluctuation) width of the specific heat “jump” of similar superconductor at similar conditions equals some percent H_{c2} [4]. Therefore the discrepancy of the width of the transition into the Abrikosov state with the width of critical region at H_{c2} could be found at measurement of the resistive properties only high quality samples.

It was difficult to find this discrepancy in conventional superconductors first of all because of relatively narrow fluctuation region. The width of the critical region, where fluctuations are strong and its interaction is essential, can be estimated by the Ginzburg number. Its value in

FIG. 19: Comparison of the resistive transition of bulk conventional superconductor V_3Ge and bulk HTSC $YBa_2Cu_3O_{7-x}$. The paraconductivity regime above H_{c4} (T_{c4}) and the sharp change of the resistive properties at the transition into the Abrikosov state are clearly observed in both superconductors. The line on the left figure is the theoretical dependence for paraconductivity in the Hartree approximation.

conventional superconductors is enough small. Without magnetic field, for example, for V_3Ge it equals approximately $Gi \approx 10^{-6}$. This means that width of the critical region at T_c is very narrow. It is important that in a magnetic field, at H_{c2} , the critical region widens essentially because of the reduction of the effective dimensionality. Because of it the Ginzburg number for H_{c2} is $Gi_H = Gi^{1/3}(th)^{2/3}$. For example $Gi^{1/3} \approx 10^{-2}$ at $Gi \approx 10^{-6}$. Therefore the dependencies of the specific heat [4,7] and magnetization [54] can be measured in the critical region near H_{c2} in contrast to the one near T_c .

One of the characteristic features of HTSC discovered after 1986 is more value of thermal fluctuations. One should note that it is not connected with the higher critical temperature. The higher T_c value is compensated in the Ginzburg number $Gi = (k_B T_c / H_c^2(0) \xi^3(0))^2$ by higher value of the thermodynamic critical field $H_c(0)$. The relation $T_c / H_c^2(0)$ can be even smaller in HTSC than in conventional superconductors. Thermal fluctuations are more appreciable in HTSC first of all because of small value of the coherence length $\xi(0)$. Fluctuation effects become stronger in layered HTSC, such as $BiSrCaCuO$, because of lesser dimensionality (in a high magnetic field perpendicular to layer it is zero-dimensional). In this Section only bulk HTSC, $YBa_2Cu_3O_{7-x}$ is considered.

The region of the mixed state without phase coherence below H_{c2} in $YBa_2Cu_3O_{7-x}$ is much wider than in conventional bulk superconductors. Therefore the difference of the “kink” position from H_{c2} arrests one’s attention. The resistance decrease because of the paraconductivity before the transition is more appreciable in HTSC than in conventional superconductor: $R(H = H_{c4}) \approx 0.83 R_n$

FIG. 20: The current voltage curves $E(j)$ of some bulk type II superconductors with weak pinning in different values of perpendicular magnetic field close to H_{c2} : a) V_3Ge , $T = 4.2$ K, $H_{c2} = 2.6$ T, $\kappa = 20$, at $H/H_{c2} \gg 1$ (1), $H/H_{c2} = 0.987$ (2), 0.940 (3), 0.925 (4), 0.918 (5), 0.910 (6), 0.894 (7); b) V_3Ge , $T = 4.2$ K, $H_{c2} = 4.4$ T, $\kappa = 40$, at $H/H_{c2} \gg 1$ (1), $H/H_{c2} = 1.000$ (2), 0.980 (3), 0.977 (4), 0.970 (5), 0.922 (6); c) $Ti_{84}Mo_{16}$, $T = 2.35$ K, $H_{c2} = 4.3$ T, $\kappa = 67$, at $H/H_{c2} \gg 1$ (1), $H/H_{c2} = 1.000$ (2), 0.977 (3), 0.954 (4), 0.907 (5), 0.861 (6); d) $Nb_{94.3}Ge_{5.7}$, $T = 1.96$ K, $H_{c2} = 0.66$ T, $\kappa = 3$, at $H/H_{c2} \gg 1$ (1), $H/H_{c2} = 1.000$ (2), 0.997 (3), 0.994 (4), 0.988 (5), 0.975 (6) [51]. The curves 5 and 6 for b) and d) are shifted along the j axis.

in V_3Ge and $R(H = H_{c4}) \approx 0.2R_n$ in $YBa_2Cu_3O_{7-x}$, Fig.19. But it is important that there is not qualitative difference between $YBa_2Cu_3O_{7-x}$ and conventional bulk superconductors. It is obvious that the same transition is observed in both cases since the same qualitative changes of the resistive properties are observed and the difference of the $(H_{c2} - H_{c4})$ values conforms the scaling law of the LLL approximation.

Unfortunately the shape change of the resistive properties (the “kink”) observed in $YBa_2Cu_3O_{7-x}$ is interpreted as vortex lattice melting [10-14]. This interpretation is very popular [58-64,86-99] but it can not be correct [100,101]. In ten years before the first observation of the “kink” in $YBa_2Cu_3O_{7-x}$ [10-12] the correct interpretation of the shape feature of the resistive properties observed below H_{c2} was proposed [8]. This interpretation of the resistive phenomenon connected with vortex pinning appearance as the transition into the Abrikosov state is correct in any case. It could coincide with the vortex lattice melting interpretation if the Abrikosov state is vortex lattice with spontaneous crystalline long-range order. But the Abrikosov state is first of all the mixed state with long-range phase coherence.

It is important that according to the habitual definition of phase coherence used by all theorists the long-

range phase coherence can not exist in the Abrikosov state without the crystalline long-range order of vortex lattice. It is main reason preserved delusion about vortex lattice melting among theorists. If the long-range phase coherence can not exist without the crystalline long-range order then there is not a difference between vortex lattice melting and the phase transition from the Abrikosov state at which the long-range phase coherence disappears. Therefore it is important to emphasize once again that the definition of phase coherence by the correlation function is not valid for the multi-connected mixed state. According to the correct definition of phase coherence (21), natural for the Abrikosov state, the existence of long-range coherence does not depend on any order of vortex distribution. Therefore two phase transition could be observed on the way from the Abrikosov state into the normal state if the Abrikosov state is vortex lattice with spontaneous crystalline long-range order.

Experimental evidence of the first order phase transition observed at H_{c4} is considered as main beyond argument that vortex lattice melting exists since this melting should be first order phase transition according to most theories. But as it is shown above phase coherence disappearance should be also first order phase transition. Therefore if vortices could form spontaneous crystalline order than two first order phase transitions should be observed on the way from the Abrikosov state into the normal state. But only phase transition is observed on this way. It is obvious that it is phase coherence disappearance since just at this transition the non-dissipation current can disappear.

6.3. Vortex creep induced by thermally activated depinning of vortices just below H_{c4} .

The energy dissipation is absent in the Abrikosov state when an applied electric current does not exceed a critical value, $j < j_c$. The value of the critical current is determined first of all by a force of vortex pinning j_p . According to the relation (12) the vortex velocity $v_{vor} > 0$ at $f_L = jH > f_p$, i.e. $j_c = f_p/H$. The j_c value can change with the applied current and real current-voltage curves may have intricate form [51]. A typical current-voltage curve has three different regime: $j < j_{cs}$ where the voltage equals zero, an intermediate regime where the current-voltage curve is non-linear and the linear regime $E = \rho_f(j - j_{cd})$ observed at an enough high current. The static j_{cs} and dynamic j_{cd} critical currents have different values. The static critical current is measured in practice by a voltage level V_l . The value j_{cs} can depend strongly or weakly on the V_l value at different conditions Fig.21.

The dependence can be strong because of vortex creep induced by thermally activated depinning of vortices. The HTSC stand out against a background of conventional superconductors by strong vortex pinning. But it is not qualitative difference. A noticeable vortex creep was observed near H_{c4} in conventional bulk superconductors Fig.22. It is interesting that in this case the vortex creep is combined with the “peak effect” observed

FIG. 21: The current voltage curves of V_3Ge , single-crystal ($T = 4.2$ K, $H_{c2} = 2.6$ T, $\kappa = 20$) in perpendicular magnetic field $H/H_{c2} = 0.82$, corresponded the region below the peak of the $j_c(H)$ dependence (a) and $H/H_{c2} = 0.95$, corresponded the top of the peak (b) [51].

in the critical current dependence, Fig.23. Both the creep increase and the “peak effect” can be explained by the decrease of the correlated volume of pinning V_p because of the softening of elastic modulus of the vortex lattice near H_{c2} . According to the theory of weak collective pinning [102] the average collective pinning force can be estimated by a relation $F_p = j_c H = (W/V_p)^{1/2}$. Where $W = n_p < f_{p,i}^2 >_{pins}$ is the average pinning force squared, with n_p the volume density of pins and $f_{p,i}$ the actual force exerted by the i th pin on the vortex lattice. The sizes of the correlated volume across $R_p = 8\pi r_p 2c_{44}^{1/2} c_{66}^{3/2} / W$ and along $L_p = (c_{44}/c_{66})^{1/2} R_p$ magnetic field depend on the elastic modulus c_{44} and c_{66} . Here r_p is the range of the pinning forces. The narrow peak of the $j_c(H)$ dependence is observed near the second critical field since $c_{66} \rightarrow 0$ at $H \rightarrow H_{c2}$ [103] and the collective pinning result goes over into the direct summation $F_p \approx n_p f_p$.

The peak effect of the true critical current measured by magnetization irreversibility, Fig.23, may transform with temperature increase into the one of untrue critical current Fig.21 because of the vortex creep Fig.22. According to the creep theory by Kim and Anderson [104] the electric field $E(T, H, j)$ caused by thermally activated

FIG. 22: The current voltage curves, $\lg(E)$ on j , of V_3Ge single-crystal at $T = 4.2$ K ($H_{c2} = 2.6$ T) in different values of perpendicular magnetic field: $H/H_{c2} \gg 1$ (1) (normal resistance), $H/H_{c2} = 0.960$ (2), 0.952 (3), 0.946 (4), 0.940 (5), 0.933 (6), 0.925 (7), 0.821 (7). The solid lines (2), (3), (4) are the theoretical dependencies obtained from the Kim-Anderson relation (22) with $E_0 = 657$ nV/cm, $j_0 = 7$ A/cm² (2), $E_0 = 350$ nV/cm, $j_0 = 10$ A/cm² (3), $E_0 = 29$ nV/cm, $j_0 = 9$ A/cm² (4) [51].

vortex jumps out of pinning centers equals

$$E(j) = E_0 \sinh\left(\frac{j}{j_0}\right) \quad (22)$$

Where $E_0 = \rho_p j_p \exp(-U/k_B T)$; $j_0 = j_p k_B T / U$; ρ_p and j_p are phenomenological parameters; $U(T, U)$ is activation energy for vortex jumps [59]. The value U of the activation energy for vortex jumps is proportional to an activated (jumping) volume of the vortex lattice which can jump independently. The activated volume, as well as the correlated volume, decreases at $H \rightarrow H_{c2}$. Therefore the peak effect observed at a high temperature may be no true, Fig.21. It can be observed on the j_{cs} dependencies measured by a high voltage level V_l and can be absent at a lower V_l . For example, according to the current-voltage curves for a single-crystal V_3Ge sample ($T_c = 6.1$ K) measured at $T = 4.2$ K (see Fig.22) the peak effect is observed at $V_l > 10$ nV/cm and is absent at $V_l < 10$ nV/cm. The peak effect of the true critical current appears in this sample at lower temperature. For example, at $T = 2.37$ K the critical current value measured by magnetization irreversibility, Fig.23, increases from $j_{cs} = 20$ A/cm² at $H \approx 0.8H_{c2}$ up to $j_{cs} = 900$ A/cm² at $H \approx 0.9H_{c2}$. The low, but finite resistance because of the vortex creep gives an feature of the dynamic magnetic susceptibility in the region of the peak effect (see Fig.7 and [54]).

There is a question: “Could the true critical current be observed just below H_{c4} ?” According to the data presented on Fig.22 and Fig.23 it is absent both at $T = 4.2$ K and $T = 2.37$ K. But it does not mean that the true critical current can be observed just below H_{c4} in any case. Since sizes of the correlated volume V_p are inversely proportional to the average pinning force squared W we can expect that it is possi-

FIG. 23: Dependencies of the magnetization M (a) and the critical current density j_c measured at $E = 100$ nV/cm (b) on the magnetic field of V_3Ge single-crystal at $T = 2.37$ K ($H_{c2} = 4.8$ T). The value of the true critical current evaluated from the magnetization irreversibility is $j_c = 20$ A/cm² below of the peak and the maximum value at the peak is $j_c = 900$ A/cm². The first is close to the one on (b). The high values $j_c > 200$ A/cm² were not measured by the resistive method because of overheating [51].

ble in a sample with very weak pinning disorders. For example if the vortex pinning takes place only on sample boundaries than the correlated volume should equal the volume of the sample. It should be emphasized that the absence of the true critical current because of the vortex pinning does not mean the absence of long-range phase coherence. Therefore rather the transformation of the current-voltage curves from Ohmic $E = \rho j$ to non-Ohmic $E = \rho_f(j - j_{cd})$ than the appearance the true non-dissipation current can be experimental evidence of the transition into the Abrikosov state.

6.4. Sharp change of the vortex flow resistance at the transition into the Abrikosov state.

It is important that the slope of the linear part of the current-voltage curves, i.e. the vortex flow resistance ρ_f , decreases sharply at H_{c4} simultaneously with the $j_{cd} > 0$ appearance, Fig.20. According to the mean field approximation the transition to the vortex flow regime occurs at H_{c2} . and the vortex flow resistance, ρ_f , near H_{c2} can be described by the relation

$$\frac{\rho_f}{\rho_n} = \gamma \left(1 - \frac{H}{H_{c2}}\right) \quad (23)$$

ρ_n is the resistance in the normal state. The coefficient γ was calculated in many works (see [67]). According to (23) the resistivity of ideal superconductor does not

FIG. 24: Dependence of the vortex flow resistance on the magnetic field of $Ti_{84}Mo_{16}$ sample at $T = 2.35$ K [51]. The peak effect in the critical current is absent in this sample (see the current voltage curves on Fig.20c). Lines are mean field approximation theoretical dependencies.

change at the long-range phase coherence appearance in H_{c2} .

The fluctuations change qualitatively the vortex flow resistance $\rho_f(H)$ dependence. First of all they displace the transition into the Abrikosov state and consequently the vortex flow regime from H_{c2} to H_{c4} . Between H_{c2} and H_{c4} the paraconductivity regime is observed as well as above H_{c2} . In additional, according to the fluctuation theory the value the vortex flow resistance near the transition should be lower than the one predicted by the mean field approximation (23) as well as the resistance above the transition is lower than the normal one ρ_n . Thus, the thermal fluctuations decrease the resistance value both above and below the transition even without taking into account the vortex pinning. This effect should increase near the transition. Therefore, a feature ought be expected at H_{c4} , i.e. at the transition from the paraconducting regime to the vortex flow regime. According to the Maki-Takayama theory [36] the decrease of the resistance in the vortex flow regime because of the fluctuations should exceed the one above the transition. Therefore the feature of the vortex flow resistance should be enough noticeable.

The detailed investigations made in [51] have shown that the feature is indeed observed in all enough homogeneous bulk samples of conventional superconductors used in this work (see Fig. 5 in [45] and Fig.24, Fig.25. The feature is absent and the $\rho_f(H)$ dependence is like to the one predicted by the mean field approximation (23) only in no enough homogeneous sample, Fig.26, or sample with no enough weak pinning disorders. In all high

FIG. 25: Dependence of the vortex flow resistance on the magnetic field of single-crystal $Nb_{94.3}Ge_{5.7}$ sample at $T = 1.96$ K. The line is the mean field approximation theoretical dependence. The peak of the critical current dependence (shown in the bottom) is considerably narrower than the step of the $\rho_f(H)$ dependence for this sample [51].

quality samples a sharp change of vortex flow resistance was observed at H_{c4} and the step, Fig.24,25, or even a minimum, Fig. 5 in [45], were observed on the $\rho_f(H)$ dependencies below the transition into the Abrikosov state. Such dependence differs qualitatively from the one (23) predicted by the mean-field approximation [67].

Because the step or minimum of the $\rho_f(H)$ dependence is observed near H_{c4} where the peak effect of the critical current may be observed the position of these two features coincides in some samples [54,105-108]. Therefore some authors [109] connect the feature of the $\rho_f(H)$ dependencies with the $j_{cs}(H)$ peak effect in the critical current. It should be noted that the peak effect can not be a cause of the $\rho_f(H)$ feature, as anybody assumes, since the latter is observed in samples both with [54,105-108] and without Fig.24 the peak effect. The width of these two features can considerably differ in some samples, Fig.25.

It is important to note at the consideration of HTSC and two-dimensional superconductors that the step or minimum of the $\rho_f(H)$ dependence is observed below H_{c4} but not below H_{c2} . The difference $H_{c2} - H_{c4}$ is no very visible in conventional bulk superconductors whereas in HTSC and in thin films it can be very visible. Therefore one should expect to observe the $\rho_f(H)$ feature no at H_{c2} but below the field at which the current-voltage curves become non-Ohmic because of phase coherence appearance. In order to measure correctly the $\rho_f(H)$ dependence one should have homogeneous samples with enough weak pinning disorders. The small value of the critical current in most HTSC samples does not mean that pinning disorders are enough weak in these samples

FIG. 26: Dependence of the vortex flow resistance on the magnetic field of an inhomogeneous $Ti_{84}Mo_{16}$ sample at $T = 2.35$ K. The width of the resistive transition in perpendicular magnetic field $\Delta H \approx 0.08H_{c2}$ of this sample exceeds considerably the one $\Delta H \approx 0.01H_{c2}$ of the homogeneous sample, Fig.24. The line is the $\rho_f(H)$ dependence for homogeneous sample, Fig.24, averaged by different H_{c2} values in the region $0.08H_{c2}$ [51].

since the j_{cs} value is small in HTSC because of strong vortex creep. The quality of HTSC samples does not reach for the present the one of conventional superconductors. Nevertheless the step just below the transition into the Abrikosov state was observed recently [110] on the $\rho_f(H)$ dependence obtained from complex impedance measurements in an untwinned $YBa_2Cu_3O_{7-x}$ crystal, Fig.27. This step called unexpected in this paper [110] although it can be expected from the results of investigations of conventional superconductors [45,51]. The step is manifested in [110] no so distinctly as in high quality samples conventional superconductors [45,51] but this result confirms one again that there is not qualitative difference between fluctuation phenomena in $YBa_2Cu_3O_{7-x}$ and conventional bulk superconductors. One should remember that the $\rho_f(H)$ feature below H_{c4} can be observed only in high quality samples and disorders can smear it.

The observation of the $\rho_f(H)$ feature just below H_{c4} of bulk superconductors corroborates the prediction of the Maki-Takayama theory [36]. It is very important for the interpretation of the nature of the Abrikosov state since according to the results [36] the mean field approximation is not valid for infinite homogeneous superconductor, i.e. just for that ideal case for which the Abrikosov solution [1] was obtained. According to [36] the fluctuation correction $\Delta\sigma_{H < H_{c2}}$ to the vortex flow conductivity is

$1.4 \ln(L/\xi)$ times the paraconductivity $\Delta\sigma_{H>H_{c2}}$ above H_{c2}

$$\Delta\sigma_{H<H_{c2}} = 1.4 \ln(L/\xi) \Delta\sigma_{H>H_{c2}} =$$

$$1.4 \ln(L/\xi) C_{\perp}(t) \sigma_0 |H/H_{c2} - 1|^{-1/2} \quad (24)$$

where $\sigma_0 = [\pi e^2 / 2^{3/2} \hbar \xi(0)]$, $1/\sigma_0 \approx 3.7 \cdot 10^4 \xi(0) \Omega cm$; $C_{\perp}(t)$ is a dependence (calculated in [52]) increasing with $t = T/T_c$, from $C_{\perp} = 0$ at $T = 0$ to $C_{\perp} \approx 0.1$ at $t = 0.5$, to $C_{\perp} \approx 1$ at $t = 0.9$ and so on at $T \rightarrow T_c$. It is important that the fluctuation correction (24) calculated in the linear approximation depends on superconductor size L across magnetic field. The dependence (24) does not mean that the resistance in the Abrikosov state $\rho_{H<H_{c2}} = \rho_f / (1 + \Delta\sigma_{H<H_{c2}} \rho_f)$ equals zero without vortex pinning in infinite superconductor $1/L = 0$ or at $H = H_{c2}$. Here ρ_f is the vortex flow resistance calculated in the mean field approximation. It means only that the linear approximation, as well as the Abrikosov solution, are not valid in the region where fluctuations are strong. The L/ξ value is very large in a real case but $\ln(L/\xi)$ is not so large. For example, at size of the V_3Ge samples used in [45] $L \approx 1 \text{ mm}$ and the coherence length $\xi \approx 10^{-5} \text{ mm}$, $L/\xi \approx 100000$ and $\ln(L/\xi) \approx 11.5$. At parameters of the V_3Ge samples: $\sigma_n = 1/\rho_f \approx 36000 (\Omega cm)^{-1}$; $\sigma_0 \approx 400 (\Omega cm)^{-1}$; the relation (24) gives for $t = T/T_s = 4.2/6.1 = 0.69$ when $C_{\perp}(t) \approx 0.27$

$$\Delta\sigma_{H<H_{c2}}/\sigma_n \approx 0.05(1 - H/H_{c2})^{-1/2} \quad (25)$$

According to this relation and (23) the $\rho_{H<H_{c2}}(H) = \rho_f / (1 + \Delta\sigma_{H<H_{c2}} \rho_f)$ dependence should have a maximum at $1 - H/H_{c2} \approx 0.04$. The position of the maximum is closed in order of value to the width of the step of the $\rho_f(H)$ dependence observed in the V_3Ge samples at $T = 4.2 \text{ K}$ [45]. It is impossible to describe more exactly the $\rho_f(H)$ feature since the result [36] obtained in the linear approximation is not valid in this region where fluctuations are strong and fluctuation interaction should take into account.

The thermal fluctuations decreases the vortex flow resistance in whole range below H_{c4} . But the $\Delta\sigma_{H<H_{c2}}/\sigma_n$ value can be visible only when fluctuations become enough strong and the linear approximation, i.e. the Maki-Takayama result [36] becomes not valid. It takes place in the critical region before the transition from the Abrikosov state. Therefore the $\rho_f(H)$ feature (the step) should be observed (and is observed [51,110]) below H_{c4} but not below H_{c2} . Above H_{c4} the Maki-Takayama theory [36], as well as the mean field approximation of the vortex flow resistance theory [67], can not be valid since any vortex theory can not be valid in the mixed state without vortices. The both theories is not valid not only just below H_{c2} but even just below H_{c4} . It was not take into account by Maki and Thompson which supposed that the Maki-Takayama result [36] contradicts to

FIG. 27: The vortex flow resistance of an untwinned $YBa_2Cu_3O_{7-x}$ crystal extracted in [110] from the complex impedance measurements.

the smooth monotonic decrease of resistance observed in HTSC below H_{c2} and tried to correct it making an important mistake [37]. The authors of [111] write that the infrared divergences in certain quantities in [36] the perturbation theory was abandoned. They have shown that these divergences cancel in physical quantities [112,113]. Indeed, the result [37] does not mean that the fluctuation corrections to any physical quantities are infinite in an infinite superconductor or at $H = H_{c2}$. This result means only that the linear approximation of the fluctuation theory as well as the mean field approximation are not valid for the infinite superconductor and near and above H_{c4} .

Because of absence of the vortex flow theory valid near H_{c4} it is not quite clear how the vortex flow resistance should change at H_{c4} in an ideal case. The experiment shows that the slope of the current-voltage curves can change by jump in high quality (homogeneous and weak pinning) bulk samples, [45,51], Fig.20,24,25, and more smooth [51] in samples with not enough high quality. Only smooth the $\rho_f(H)$ dependence at H_{c4} was observed for the present in $YBa_2Cu_3O_{7-x}$ [110], Fig.27 and it is not quite clear one could observe more sharp change of the $\rho_f(H)$ value at H_{c4} of $YBa_2Cu_3O_{7-x}$ in which fluctuation value is much higher than in conventional bulk superconductor. The step of the $\rho_f(H)$ dependence is observed just below H_{c4} at which the current-voltage curves become non-Ohmic. Although the values are very different in these superconductors. The $\rho_f(H)$ feature is observed at an interval of fluctuation value in which thermal fluctuations are enough strong in order to decrease appreciably the vortex flow resistance but are not enough strong in order to destroy long-range phase coherence and induce the transition from the Abrikosov state. This interval corresponds to different H/H_{c2} value in superconductors with different value of fluctuations. One

may say that the $\rho_f(H)$ feature should be observed in a region where the linear approximation of the fluctuation theory becomes not valid but the Abrikosov state still remains, i.e. just below H_{c4} .

According to the Maki-Takayama theory [36] the thermal fluctuations in the two-dimensional Abrikosov state are much stronger than in the three-dimensional one. The value of fluctuation correction in the Abrikosov state calculated in the linear approximation is $1.4 \ln(L/\xi)$ times the one in the normal state for bulk superconductor with $L_z \gg \xi$ and is $(L/\xi)^2$ times the one for thin film with $L_z < \xi$. Here L_z is superconductor size along magnetic field. The difference between the values is enormous in a real case. For example at a superconductor size across magnetic field $L \approx 1 \text{ mm}$ and the coherence length $\xi \approx 10^{-5} \text{ mm}$, $\ln(L/\xi) \approx 11.5$ and $\ln(L/\xi) \approx 10^{10}$. The difference remains enormous even for a thin film microstructure with $L_{\text{approx}} 1 \mu\text{m}$. This means that the linear approximation of the fluctuation theory [36] as well as the Abrikosov solution are not valid for the mixed state of thin films with $L_z < \xi$.

Thus, the boundary of the linear approximation [36] applicability shifts from magnetic field value correspond some per cent below H_{c2} for bulk ($L_z \gg \xi$) conventional superconductors to zero magnetic field for thin film with $L_z < \xi$. One may expect that in an intermediate case between $L_z \gg \xi$ and $L_z < \xi$ this boundary and the $\rho_f(H)$ feature, connected with it, can shift with a change of film thickness L_z . The position of the $\rho_f(H)$ feature in films of conventional superconductors depends indeed from film thickness. For example, the investigations [106] of amorphous $Nb_{1-x}Ge_x$ films, a superconductor with a small coherence length $\xi(0) \approx 7 \text{ nm}$, have shown that the $\rho_f(H)$ feature is observed at $H \approx 0.9H_{c2}$ in a film with thickness $L_z = 2350 \text{ nm}$, at $H \approx 0.82H_{c2}$ with $L_z = 565 \text{ nm}$, at $H \approx 0.75H_{c2}$ with $L_z = 205 \text{ nm}$ and at $H \approx 0.62H_{c2}$ with $L_z = 92.5 \text{ nm}$. It is important that the $\rho_f(H)$ feature is observed below H_{c4} at which the current voltage curves become non-Ohmic.

6.5. Absence of the transition into the Abrikosov state in two-dimensional superconductors with weak disorder down to very low magnetic field.

The shift of the position of the $\rho_f(H)$ feature [106] and the resistive transition [114] to lower H/H_{c2} values at the decrease of film thickness means that the difference between H_{c2} and the position of the transition into the Abrikosov state H_{c4} increases in thin films. This experimental result collaborate the difference of fluctuation effects in the Abrikosov state of three- and two-dimensional superconductors predicted by the Maki-Takayama theory [36]. According to this theory the Abrikosov state can be absent or observed only at very low magnetic field $H \ll H_{c4}$ in two-dimensional superconductors i.e. in film with $L_z < \xi$.

It is important to note that the $\rho_f(H)$ feature and the dependence of its position from film thickness can be observed only in samples with enough weak pinning.

FIG. 28: The magnetic dependence of the resistance of the amorphous NbO_x film structure with thickness $d = 20 \text{ nm}$, width $w = 10 \text{ mm}$ and length $L = 2.25 \text{ mm}$. In the inset the current-voltage curves in perpendicular magnetic fields, $H = 0, 100 \text{ Oe}, 200 \text{ Oe}, 4 \text{ kOe}$, are shown. $T = 1.6 \text{ K}$, $H_{c2} = 16.8 \text{ kOe}$ [46].

The transition into the Abrikosov state in samples with strong pinning disorders differs qualitative from the one with weak pinning (see [115] and below). The importance of pinning disorders for stabilization of the Abrikosov state is obvious already from the consideration of fluctuation influence in the Eilenberger's conception (see Section 2.6). It is obvious that disorders breaking displacement symmetry can stabilize the Abrikosov state as well as a finite size of superconductor L .

There is possibility to compare experimental results obtained for thin films of amorphous $a - Nb_3Ge$ [109] and of amorphous NbO_x [46] with closed parameters, $L_z = 18 \text{ nm}$, $\xi(0) = 7.4 \text{ nm}$, $T_c = 2.91 \text{ K}$ in the first case and $L_z = 20 \text{ nm}$, $\xi(0) = 7.8 \text{ nm}$, $T_c = 2.37 \text{ K}$ in the second case, but with slightly different amount of pinning disorders. In the $a - Nb_3Ge$ film at $T = 1.55 \text{ K}$ the current voltage curves become non-Ohmic at $H \approx 0.45H_{c2}$ ($H \approx 1.2 \text{ T}$) and below this field the $\rho_f(H)$ feature is observed, Fig.7 in [109]. In the NbO_x film at $T = 1.6 \text{ K}$ the current voltage curves remain Ohmic down to $H = 0.006H_{c2}$ ($H \approx 0.01 \text{ T}$) and the $\rho_f(H)$ feature is not observed, Fig.28. On base of the measurements made in [46] the static critical current is absent at $H \approx 0.01 \text{ T}$ to within 10000 A/m^2 and at $H \approx 0.4H_{c2}$ to within 200 A/m^2 . The critical current the NbO_x film appears at $H < 0.003H_{c2}$ and increases in a narrow interval of the magnetic field from $j_c < 10^4 \text{ A/m}^2$ at $H = 0.005 \text{ T}$ to $j_c > 10^{10} \text{ A/m}^2$ at $H = 0$ (at $T = 1.6 \text{ K}$, $H_{c2} = 2.2 \text{ T}$). Such immense change of the critical current in a low magnetic field $H \ll H_{c2}$ is evidence of extremely weak pinning. The weak $j_c(H)$ dependence of low critical current of some HTSC samples observed in low magnetic field is evidence of weak links but not weak pinning.

The appearance of the critical current in the NbO_x films at very low magnetic field $H < 0.003H_{c2}$ may be

interpreted as the transition into the Abrikosov state. But an incomprehensible anomaly is observed in this region [116]. It is impossible to understand for the present why the peaks of the resistance dependence $R(H)$ of the NbO_x strips can be observed in low magnetic field $H < 0.003H_{c2}$ and why the resistance can considerably exceed the vortex flow resistance. But it is important that the width of the anomaly H_w and the peak position H_p are inversely proportional to width of the strip w_{st} : $H_w = 0.0006 T$ and $H_p = 0.0002 T$ for the NbO_x strip with $w_{st} = 50 \mu m$ and $H_w = 0.004 T$ and the position of main maximum $H_p = 0.001 T$ for the NbO_x strip with $w_{st} = 10 \mu m$ [116]. It gives a possibility to assume that the anomaly observed in thin films with extremely weak pinning disorders may be connected with a vortex pinning on strip boundaries. This may mean that vortex pinning is only on superconductor boundaries in the amorphous NbO_x films used in [46].

Comparison of the critical current values shows that the amorphous $a - Nb_3Ge$ film used in [109] has no so weak pinning disorders as the amorphous NbO_x films used in [46]. For example, the dynamic critical current j_{cd} is absent to within $200 A/m^2$ at $H \approx 0.4H_{c2}$ in the NbO_x films whereas the $a - Nb_3Ge$ film (see Fig.7 [109]) in the current voltage curves are appreciably non-Ohmic at this magnetic field in the used interval of the measuring current density $1500 \div 4.5 \cdot 10^5 A/m^2$. The observation of the $\rho_f(H)$ feature at $H \approx 0.4H_{c2}$ in the amorphous $a - Nb_3Ge$ film with weak pinning (Fig.7 [109]) and the absence of any $\rho_f(H)$ feature down to $H = 0.006H_{c2}$ in the amorphous NbO_x films with weaker pinning are evidence of strong influence of pinning disorders on the position of the transition into the Abrikosov state of thin films which can be considered as two-dimensional superconductor.

Authors of [109] state that the transition into the Abrikosov state is not observed in [46] since the critical current in the amorphous NbO_x films is extremely small in comparison to the measuring current and therefore the appearance of vortex pinning can not be visible. Indeed, the transition from the Ohmic, $E = \rho j$, to non-Ohmic, $E = \rho_f(j - j_{cd})$, regime can be not visible if $j_{cd} \ll j$. But the $\rho_f(H)$ feature observed near the transition into the Abrikosov state in all enough high quality sample should be observed at any relation j_{cd}/j . The $\rho_f(H)$ feature is observed at the transition into the Abrikosov state in the $a - Nb_3Ge$ film (see Fig.7 [109]) with an intermediate amount of pinning disorders. Therefore it should be manifested more distinctly at this transition in the NbO_x films with weaker pinning since all investigations show that the $\rho_f(H)$ feature is manifested more distinctly in high quality samples with weaker pinning. The absence of this feature the amorphous NbO_x films, Fig.28, is evidence of the absence of the transition into the Abrikosov state down to $H = 0.006H_{c2}$ [46].

It is shown in the Sections 5.3, 5.4 that the dependence of the values connected only with average density of superconducting pairs should obey the scaling law in

FIG. 29: Dependencies of the excess conductivity on temperature $\Delta\sigma(T)$ of the amorphous NbO_x film in the co-ordinates following from the scaling law of the LLL approximation in different magnetic fields [46]. The line denotes the theoretical dependence of paraconductivity obtained in the Hartree approximation of fluctuation theory.

the region where the LLL approximation is valid. The resistive properties depends first of all on existence or absent of phase coherence. But one may expect that the paraconductivity may also obey the scaling law not only above H_{c2} but also below H_{c2} , until the mixed state without phase coherence remains. It was shown in [46] that the temperature dependencies of the excess conductivity $\Delta\sigma(T)$ of the amorphous NbO_x films measured at different field $H = 0.1 - 1.2 T$ obey the scaling law and are close to the theoretical dependence for paraconductivity calculated in the Hartree approximation down to temperature considerably lower T_{c2} , Fig.29. The existence of phase coherence should cause a deviation of the $\Delta\sigma(T)$ dependencies from the scaling law. This deviation can be evidence of phase coherence appearance. The absence of the deviation on Fig.29 confirms one again that that phase coherence is absent both above and below H_{c2} of the amorphous NbO_x films used in [46]. It is important to note that the scaling law is observed below H_{c2} only in superconductors with enough weak pinning. The deviation from the scaling law can be observed already above H_{c2} in films with strong pinning [115], Fig.35. The deviation from the scaling law observed in [109] may be also connected with phase coherence appearance induced by pinning disorders.

6.6. Experimental confirmation of phase coherence absence below H_{c2} of thin films with weak pinning disorders.

The absence of phase coherence below H_{c2} in the amorphous NbO_x films is confirmed by a investigation of a non-local resistance [117]. The non-local resistance can be observed near the critical temperature when size of superconducting drops becomes close to sizes of a microstructure. The potential difference measured on the

FIG. 30: The temperature dependencies of voltage relation, V/V_n , on different potential contacts in zero magnetic field. $I = 2 \mu A$. The NbO_x film ($d = 20 \text{ nm}$) structure and the location of the potential contacts are shown schematically in the inset. The width of the strip and branch equals $4 \mu m$ [117].

branch of the strip with a current of the microstructure shown on Fig.30 should depend on the distance from the strip because of the gradient of the current density leaking in the branch. For the amorphous NbO_x microstructure with the branch length equals $8 \mu m$ and the width of the branch and strip equals $4 \mu m$ the potential difference between contacts 3-3, 4-4 and 2-2 equal in the normal state, at temperature much higher T_c : $V_{33,n} = I \times 185 \Omega$, $V_{44,n} = I \times 111 \Omega$ and $V_{22,n} = I \times 60 \Omega$. The temperature dependencies of the relation $v_{ii}(T) = V_{ii}(T)/V_{ii,n}$ (see Fig.30) show that the gradient of the current density leaking in the branch decreases near T_c . The reduction of the gradient takes place because no current gradient should be inside superconducting drops according to (8). The integral of superconducting current j_s along a closed path inside a drop $\oint dl j_s = 0$ since $\oint dl \nabla \varphi = 0$ and $\Phi = 0$ without external magnetic field and at weak screening, i.e. when the magnetic field induced by superconducting current j_s is neglected low. The gradient of the current density decreases since size of superconducting drops increases near T_c .

The screening in a superconducting structure is weak when its size is smaller than the penetration length of the magnetic field. The perpendicular penetration length of a thin film with thickness d equals $\lambda_{2d} = \lambda_L^2/d$. The value $\lambda_{2d} = 7.6 \mu m$ (for the amorphous NbO_x films with the London penetration length $\lambda_L(T=0) = 390 \text{ nm}$ and $d = 20 \text{ nm}$) is close to the branch sizes even at $T = 0$. The penetration length increases near T_c in many times. Therefore the gradient of the current density should be absent in any region where phase coherence exists, independently with or without the Abrikosov vortices.

The suppression of the non-local resistance observed in very low magnetic field means that magnetic field destroys phase coherence. It decreases size of superconducting drops above T_c down to $(\Phi_0/H)^{1/2}$. The decreasing

FIG. 31: The temperature dependencies of voltage relation on the potential contacts 4-4, $V_{44}/V_{44,n}$, (see the inset on Fig.29) at different values of perpendicular magnetic field [117].

of the non-local resistance, observed near the maximum of the $v_{44}(T)$ dependence, becomes to be appreciable at $H = 20 \text{ Oe} = 0.002 \text{ T}$, Fig.31. This means that superconducting drops larger than $(\Phi_0/20 \text{ Oe})^{1/2} = 1 \mu m$ contribute to the reduction of the current density gradient just above the sharp decrease of the resistance. It is enough natural since the sharp decrease of the resistance should be observed when size of superconducting drops mounts a size of the structure.

It is important to note that the magnetic field first of all destroys phase coherence. The paraconductivity value does not change appreciably up to $H = 200 \text{ Oe}$ whereas the non-local resistance is suppressed strongly in this field, Fig.31. The small change observed in the paraconductivity is consistent with small change in the mean-field critical temperature, $T_{c2} - T_c = H/(dH_{c2}/dT) = -H/(2.2 \text{ T/K})$: at $H = 20 \text{ Oe} = 0.002 \text{ T}$, $T_{c2} - T_c = -0.0009 \text{ K}$; at $H = 200 \text{ Oe} = 0.02 \text{ T}$, $T_{c2} - T_c = -0.009 \text{ K}$.

The temperature dependencies of the reduced voltage $v_{ii}(T) = V_{ii}(T)/V_{ii,n}$ measured on the branch $v_{44}(T)$ differs from the one $v_{11}(T)$ measured on the control contacts up to $H = 500 \text{ Oe} = 0.05 \text{ T}$, Fig.32. The difference is visible near T_c since the coherence length has maximum value in this region. The difference between $v_{44}(T)$ and $v_{11}(T)$ becomes not visible at $H = 2000 \text{ Oe} = 0.2 \text{ T}$. The non-local resistance is not observed both above and much below T_{c2} , Fig.32.

This means that phase coherence is absent in the amorphous NbO_x film placed in a magnetic field both above and below T_{c2} , although its resistance is appreciably lower at $T < T_c$ than $T > T_c$ Fig.32.

7. Influence of Pinning Disorders on the Nature and Position of the Transition into the Abrikosov State.

The sharp, first order phase transition into the Abrikosov state is observed only in few high quality bulk samples [8,11-14] as well as the absence of this transition

FIG. 32: The temperature dependencies of voltage relation on the potential contacts 4-4, V_{44}/V_{44n} , and 1-1, V_{11}/V_{11n} , (see the inset on Fig.30) in perpendicular magnetic field $H = 0.5 \text{ kOe}$ and $H = 2 \text{ kOe}$. $I = 2 \mu\text{A}$ [117].

down to very low magnetic field is observed only in few high quality thin films [46]. The behaviour of overwhelming majority of real samples both bulk and thin film differs qualitatively from these almost ideal cases because of pinning disorders. This difference of the behaviour of most real superconductors from an ideal case is one of the main difficult of investigation of the Abrikosov state and the reason of many errors. Pinning disorders are not only the cause of the non-dissipation current, as one assumed during long time, they change the nature of the transition into the Abrikosov state and can stabilize this state.

7.1. Pinning disorders smooth out the sharp transition observed only in high quality samples.

The possibility of an influence of disorders on the nature of the transition into the Abrikosov state is obvious from the consideration of the ideal case in the Section 6.1. The appearance of long-range phase coherence should occur through first order phase transition since only two characteristic lengths L and $(2\Phi_0/\pi H)^{1/2}$ exist across magnetic field in the ideal superconductor. Therefore the sharp change of the resistive properties is observed in few bulk samples with weak disorder. But this transition may qualitatively change in a superconductor with pinning disorders in which distance d_p between pinning centers is an additional characteristic lengths. The sharp transition should remain when $d_p \gg (2\Phi_0/\pi H)^{1/2}$. Just this takes place in real bulk samples with weak pinning [8,11-14]. But the phase coherence appearance can become a smooth transition when the distance d_p between pinning centers is comparable in order of value with $(2\Phi_0/\pi H)^{1/2}$. Therefore no sharp change is observed and the resistive transition is smooth in samples with strong disorder. The transition into the Abrikosov state becomes smooth with increasing of disorder amount and differs qualitative from the ideal case considered by Abrikosov.

The resistive transition of real type II superconduct-

FIG. 33: The resistive transition in perpendicular magnetic field of a) the amorphous NbO_x film ($d = 20 \text{ nm}$) at $H = 0$ (1), $H = 0.2 \text{ T}$ (2), $H = 0.4 \text{ T}$ (3), $H = 0.8 \text{ T}$ (4), $H = 1.2 \text{ T}$ (5); b) the $Bi_2Sr_2CaCu_2O_{8+x}$ in-plane (along ab) at $H = 0$ (1), $H = 0.044 \text{ T}$ (2), $H = 0.2 \text{ T}$ (3), $H = 0.5 \text{ T}$ (4), $H = 1 \text{ T}$ (5); and c) the NbO_x film with fine grain structure ($d = 20 \text{ nm}$) at $H = 0$ (1), $H = 0.4 \text{ T}$ (2), $H = 1.2 \text{ T}$ (3) [115].

tors may be enough diverse, Fig.33, because of different pinning disorders and other reason and can not be described by only dependence. There is a problem with detection of phase coherence appearance. The resistive dependencies may not differ qualitatively for the cases with and without phase coherence. For example, the resistive transition for the amorphous NbO_x film and the NbO_x film with fine grain structure presented on Fig.33 are qualitatively similar but in the first case of with weak pinning disorders phase coherence is absent down to low resistance value whereas in the second case of thin film with strong pinning it appears already near T_{c2} .

The non-Ohmic current voltage curves can be observed only in the mixed state with phase coherence. Therefore the non-Ohmic regime can be used as the evidence of phase coherence. The current voltage curves can become non-Ohmic in different samples at different reduced values H/H_{c2} of magnetic field. For example, it takes place at $H/H_{c2} \approx 0.002$ (at $T/T_c = 0.77$) in the amorphous NbO_x film, Fig.34. In the NbO_x film with the same thickness $d = 20 \text{ nm}$ but with fine grain structure it takes place at $H/H_{c2} \approx 0.7$ (at $T/T_c = 0.74$), Fig.34. It is well known that the current voltage curves of layered HTSC remain Ohmic down to very low magnetic field. But it is important to note that the H_{c4}/H_{c2} value in conventional thin film can be lower than in layered HTSC.

The current voltage curves of a $Bi_2Sr_2CaCu_2O_{8+x}$ sample shown on Fig.34 become non-Ohmic at a higher $H/H_{c2} \approx 0.004$ value (at $T/T_c = 0.75$) than it is observed the amorphous NbO_x film. One should emphasize that the observation of the Ohmic current voltage curves does not vouch for the absence of phase coherence. The current voltage curves can be Ohmic because of very strong

FIG. 34: Current-voltage characteristics of a) the amorphous NbO_x film ($d = 20$ nm) at $T = 1.75$ K ($T/T_c = 0.77$, $H_{c2} = 1.14$ T) and $H = 0$ (1), $H = 0.001$ T (2), $H = 0.002$ T (3), $H = 0.004$ T (4), $H = 0.006$ T (5), $H = 0.01$ T (6); b) the $Bi_2Sr_2CaCu_2O_{8+x}$ in-plane (along ab) at $T = 60$ K ($T/T_c = 0.75$, $H_{c2} = 20$ T) and $H = 0$ (1), $H = 0.02$ T (2), $H = 0.05$ T (3), $H = 0.1$ T (4), $H = 0.2$ T (5), $H = 0.4$ T (6); c) the NbO_x film with small grain structure (with $d = 20$ nm) at $T = 4.2$ K ($T/T_c = 0.74$, $H_{c2} = 0.9$ T) and $H = 0.05$ (1), $H = 0.1$ T (2), $H = 0.2$ T (3), $H = 0.4$ T (4), $H = 0.5$ T (5), $H = 0.7$ T (6) [115].

vortex creep. The Kim-Anderson expression (22) gives a linear dependence $E(j)$ at $j/j_0 \ll 1$. The thermally activated linear vortex flow resistance is observed first of all in HTSC [59].

In superconductors with strong pinning disorders the length of phase coherence $\xi_{p.c}$ changes not by jump from $(2\Phi_0/\pi H)^{1/2}$ to L as in the ideal case but continuously in any region of temperature or magnetic field values. The current voltage curves can be Ohmic in this transitional. In order to detect where the length of phase coherence $\xi_{p.c}$ becomes to differ from $(2\Phi_0/\pi H)^{1/2}$ the scaling law of the LLL approximation can be used. As it was shown in [46] (see also the Section 6.5) the temperature dependencies of excess conductivity for different magnetic field can be described by an universal law. But it is possible only without phase coherence i.e. at $\xi_{p.c} = (2\Phi_0/\pi H)^{1/2}$ since a change of the length of phase coherence should strongly influence on the conductivity. According the experimental data presented on Fig.35 the temperature dependencies of excess conductivity of the NbO_x film with fine grain structure deviate from the universal dependence describing the $\Delta\sigma(T, H)$ of the amorphous NbO_x film already above H_{c2} .

One should remember that the scaling law can be valid only in the LLL approximation region. In particular it is not valid at $h = H/H_{c2}(0) < Gi$. A LLL crossover field $H_{LLL} = H_{c2}(0)Gi$ of conventional superconductors is much lower the values of magnetic field $H = 0.1 \div 10$ T used for investigation of type II superconductors. But the LLL crossover field of layered HTSC is very high, $H_{LLL} =$

FIG. 35: Dependencies of the excess conductivity on temperature $\Delta\sigma(T)$ in the co-ordinates following from the scaling law of the LLL approximation for: the amorphous NbO_x film ($T_c = 2.37$ K; $Gi_{2D} \approx 0.0005$) at $H = 0.1$ T (1), $H = 0.4$ T (2), $H = 1.2$ T (3); the NbO_x film with small grain structure ($T_c = 5.7$ K; $Gi_{2D} \approx 0.0001$) at $H = 0.4$ T ($h = 0.11$) (4), $H = 1.2$ T ($h = 0.33$) (5) and the $Bi_2Sr_2CaCu_2O_{8+x}$ ($T_c = 79$ K; $Gi_{2D} \approx 0.02$) at $H = 0.1$ T ($h = 0.0012$) (6), $H = 1$ T ($h = 0.012$) (7) [115].

10 T for $Bi_2Sr_2CaCu_2O_{8+x}$. Therefore the discrepancy of the $\Delta\sigma(T, H)$ dependencies for $Bi_2Sr_2CaCu_2O_{8+x}$ with the scaling law, Fig.35, means only that the LLL approximation is not valid for $H = 0.1$ T and $H = 1$ T for this HTSC. The weak shift in magnetic field of the top of the resistive transition observed in layered HTSC, Fig.33, can be explained from the invalidity of the LLL approximation at $H < H_{LLL}$.

7.2. Abrikosov's model and Mendelssohn's model.

It is useful now to recall that before as Abrikosov had obtained his famous solution [1] many properties of type II superconductors were explained enough well by the Mendelssohn's model [18]. These two models have many traits in common. First of all the both models consider the mixed state of type II superconductors as multi-connected superconducting state. But Mendelssohn assumes that the multi-connected superconducting state appears because superconducting alloys are inhomogeneous whereas Abrikosov considered an ideal homogeneous superconductor. The main difference between these models is that the Abrikosov vortex destroy superconductivity near itself whereas in the Mendelssohn's model it occupies a nonsuperconducting region. Real superconductor is not ideal homogeneous as well as it is not the Mendelssohn's "sponge". Therefore the mixed state with long phase coherence of most real type-II superconductors may be considered as intermediate case between the Mendelssohn's and Abrikosov's models.

The Mendelssohn's model may be more useful for the description of superconductors with strong pinning disorders since superconducting "sponge" is the limit case

FIG. 36: Current-voltage characteristics of the NbO_x film with small grain structure (with $d = 20$ nm) at $T = 4.2$ K: $H = 0.6$ T (1) and $H = 0.4$ T (2), the amorphous NbO_x film at $T = 1.75$ K and $H = 0.004$ T (3) and the $Bi_2Sr_2CaCu_2O_{8+x}$ at $T = 60$ K and $H = 0.05$ T (4). The lines 1*, 2* and 3* denote the theoretical dependencies obtained from the Kim-Anderson relation (22) with $E_0 = 0.27$ V/m, $j_0 = 9 \cdot 10^7$ A/m² (1*), $E_0 = 0.0015$ V/m, $j_0 = 4.3 \cdot 10^7$ A/m² (2*), $E_0 = 0.05$ V/m, $j_0 = 8.6 \cdot 10^7$ A/m² (4) [115].

of strong disorder. First of all the Mendelssohn's model can explain why the transition into the Abrikosov state is continuous in superconductors with strong pinning. The phase coherence appearance in the Mendelssohn's "sponge" should be a continuous transition since the length of the phase coherence in one-dimensional superconductor does not change by jump but increases gradually with the temperature decreasing below T_c [53].

Thin film with strong pinning disorders in the Abrikosov state may be considered as a sponge of one-dimensional superconductors with a variable width $w(T, H)$ across the magnetic field which equals approximately the distance between normal cores of the vortices: $w(T, H) \approx a(\Phi_0/H)^{1/2} - 2\xi(T)$ [118]. Where a is a number of order 1, in the triangular lattice $a = 2^{1/2}/3^{1/4}$. At a low magnetic field $H \ll H_{c2}$, $w(T, H) \approx 2\xi(T)[(H_{c2}/H)^{1/2} - 1]$. This model can be valid when most vortices are disposed on the pinning centers, where superconductivity is suppressed or absent. The length of phase coherence changes smoothly in a wide region since this model is like to a one-dimensional superconductor. It depends not only on temperature but also on the magnetic field value since the width $w(T, H)$ depends both on T and H . The deviation of the $\Delta\sigma(T, H)$ dependencies of the NbO_x film with fine grain structure from the scaling law already above H_{c2} , Fig.35, can be explained qualitatively by the exceeding of the critical field of one-dimensional superconductor $H_{c,1D} = 3^{1/2}\Phi_0/\pi\xi w$ [49] of the $H_{c2} = \Phi_0/2\pi\xi^2$.

The length of the coherence of the sponge of one-dimensional superconductors increases smoothly with the T and H decrease up to $\xi_{p.c.} \gg L$ but remains finite at

non-zero temperature. At low T and H value a crossover to the vortex creep regime takes place. This crossover can be interpreted as a consequence of the increasing of the phase coherence length up to sample size. The vortex creep can take place in the Mendelssohn's model as well as it takes place in the Abrikosov state. According to the Mendelssohn's model of thin film [118] the parameters E_0 and j_0 in the Kim-Anderson relation (22) equal $E_0 = Hl_v\omega_0 \exp(\xi dw f_{GL}/k_B T)$ and $j_0 = 8\pi^2 k_B T / \xi d \Phi_0$. Here l_v is the distance between the vortices; ω_0 is an attempt frequency; f_{GL} is the density of the GL free energy, d is the film thickness. Thus, the vortex creep observed in thin film with strong pinning disorders, Fig.36, can be described by both Abrikosov and Mendelssohn's model. The dependence of the E_0 value on H/H_{c2} observed in the NbO_x film with fine grain structure can be explained by the change of the width $w(T, H)$ with H/H_{c2} [115].

7.3. Pinning disorders stabilize the Abrikosov state.

The comparison of the results presented on Fig.34 and Fig.35 shows that the appearance of phase coherence in thin films, which can be considered as two-dimensional superconductors, depends strongly on the amount of pinning disorders. The current voltage curves become non-Ohmic at $H/H_{c2} \approx 0.002$ (at $T/T_s \approx 0.77$) in the amorphous NbO_x film, at $H/H_{c2} \approx 0.45$ (at $T/T_c \approx 0.53$) in the amorphous $a - Nb_3Ge$ film [109] and at $H/H_{c2} \approx 0.8$ ($T/T_s \approx 0.74$) in the NbO_x film with fine grain structure, Fig.34. One may think that the transition from the Ohmic to non-Ohmic regime in the amorphous $a - Nb_3Ge$ film [109] is caused by the phase coherence appearance since the $\rho_f(H)$ feature is observed below $H/H_{c2} \approx 0.45$. But in the NbO_x film with fine grain structure the $\rho_f(H)$ feature is not observed and the slope of the Ohmic current voltage curve at $H/H_{c2} \approx 0.8$ differs strongly from the resistance of the amorphous NbO_x film at this reduced magnetic field. Just below $H/H_{c2} \approx 0.8$ the $E(j)$ dependencies of the NbO_x film with fine grain structure is described by the Kim-Anderson relation for the vortex creep (see the curve (1) for $H/H_{c2} \approx 0.7$ on Fig.36). Therefore the transition from the non-Ohmic to Ohmic regime in this NbO_x film should be interpreted as a consequence of the vortex creep increase (because the j/j_0 value becomes much smaller 1) but no phase coherence disappearance. The comparison of the $\Delta\sigma(T, H)$ dependencies for the amorphous NbO_x film and the NbO_x film with fine grain structure, Fig.35, shows that the phase coherence in the second case appears already above H_{c2} .

Since the parameters (thickness d , coherence length $\xi(0)$ and others) are closed in the amorphous NbO_x film, the amorphous $a - Nb_3Ge$ film [109] and the NbO_x film with fine grain structure only reason of the qualitative difference observed on Fig.34-36 can be difference amount of pinning disorders. The static critical current $j_{cs} = 10^6$ A/m² is observed at $H = 0.0012H_{c2}$ (at $T/T_c = 0.76$) in the amorphous NbO_x film and at $H = 0.45H_{c2}$ (at $T/T_c = 0.74$) in the NbO_x film with fine grain structure, Fig.37. The dynamic critical cur-

FIG. 37: The static critical current j_{cs} dependencies on the reduced magnetic field H/H_{c2} of the amorphous NbO_x film at $T = 1.75$ K (1); the $Bi_2Sr_2CaCu_2O_{8+x}$ at $T = 60$ K (2); the NbO_x film with small grain structure at $T = 4.2$ K (3). The j_{cs} values were determined by the voltage level 0.0001 V/m. $H/H_{c2} = 10^{-4}$ is corresponded to $H = 0$. $j_{cs} = 10^4$ A/m² is correspond to $j_{cs} < 10^4$ A/m² [115].

rent of the amorphous $a - Nb_3Ge$ film estimated from the data presented on Fig.7 of [109], equals in order of value $j_{cd} = 10^5$ A/m² at $H = 0.8$ T $\approx 0.3H_{c2}$ (at $T/T_c = 0.53$). For the comparison $j_{cd} < 10^5$ A/m² at $H = 0.006$ T $\approx 0.0052H_{c2}$, $j_{cd} \approx 3 \cdot 10^7$ A/m² at $H = 0.004$ T $\approx 0.0035H_{c2}$, $j_{cd} \approx 5 \cdot 10^7$ A/m² at $H = 0.002$ T $\approx 0.0017H_{c2}$ and $j_{cd} \approx 1.5 \cdot 10^8$ A/m² at $H = 0.001$ T $\approx 0.00088H_{c2}$ in the amorphous NbO_x film at $T/T_c = 0.77$, Fig.34.

This comparison of the critical current values shows that the amorphous NbO_x film has very weak strength of pinning disorders, the amorphous $a - Nb_3Ge$ film has an intermediate strength and the strength of pinning disorders of the NbO_x film with fine grain structure is very strong. We may conclude that the position of the transition into the Abrikosov state is not universal. It depends on the amount of disorder. An intermediate amount of pinning disorders displaces the transition into the Abrikosov state of two-dimensional superconductor from the region of very low magnetic field $H \ll H_{c2}$. This transition in thin film with strong pinning should be described rather by the Mendelssohn's model than the Abrikosov one. The dependence of the position of the transition into the Abrikosov state of two-dimensional superconductors on the amount of disorder is explained by results of the work [44].

8. What can be in the ideal case considered by Abrikosov?

Thus, the survey of the experimental and theoretical results shows that the taking into account of thermal fluctuations changes qualitatively interpretation of the Abrikosov state and reveals the determinant of pinning disorders in the mixed state of type II superconductors.

Because of fluctuations no the Abrikosov state but the mixed state without phase coherence is observed almost in whole region below H_{c2} of two-dimensional superconductors with enough weak pinning disorders and the transition into the Abrikosov state observed in bulk superconductors with enough weak pinning disorders is first but not second order phase transition. Pinning disorders change the nature of the this transition and displace the appearance of phase coherence in thin films from the region of very low magnetic field.

The revealed difference between bulk superconductor and thin film and also the feature of the vortex flow resistance observed below H_{c4} corroborate the results of the Maki-Takayama theory [36]. According to this theory the mean field approximation is not valid just in the ideal case of homogeneous infinite superconductor considered by Abrikosov. The Abrikosov state is observed in bulk superconductors because the fluctuation correction to the solution [2], proportional to $\ln(L/\xi)$ for three-dimensional superconductor, is small in samples with real size L at the magnetic field enough lower H_{c2} . This correction, proportional to $(L/\xi)^2$ for two-dimensional superconductor, is much larger for thin films. Therefore the Abrikosov state, i.e. the mixed state with long range phase coherence, is not observed almost in whole region below H_{c2} of thin films with very weak pinning disorders. Nevertheless the mixed state with phase coherence can be observed in thin films because of pinning disorders.

There is important question: "Can the Abrikosov state appear spontaneously in homogeneous symmetric infinite space or it is observed only because of finite size of real superconductors and pinning disorders?" The absence of phase coherence in thin films with weak pinning down to very low magnetic field $H \ll H_{c2}$ and the observation of the transition into the Abrikosov state of bulk samples at $H_{c4} < H_{c2}$, slightly above the region where the mean field approximation becomes invalid, allow to assume that in the ideal case could be no the Abrikosov state but the mixed state without phase coherence. In this case the Abrikosov state is not spontaneous but is induced by disorders and finiteness of the space in which it is observed. It has only long range order – phase coherence since the crystalline long range order of vortex lattice can not be in the space with disorders.

It would be useful for the solution of the problem about the state in the ideal infinite superconductor to measure the position of the transition into the Abrikosov state, H_{c4} , in sample with different sizes L . It is very difficult to observed the expected dependence of H_{c4} on L in bulk superconductor. The samples should differ in size L in many time in order the expected difference of H_{c4} could be visible. For example $\ln(L/\xi) \approx 11.5$ for a $YBa_2Cu_3O_{7-x}$ sample with $L = 0.1$ mm, $\ln(L/\xi) \approx 13.8$ at $L = 1$ mm, $\ln(L/\xi) \approx 16.1$ at $L = 1$ cm and $\ln(L/\xi) \approx 20.7$ at $L = 1$ m. The main difficulty is pinning disorders existing in any real sample. In this case the position should be determined by the distance between pinning disorders but not sample size.

It is even more difficult problem to describe theoretically the transition of bulk type II superconductor from the mixed state without phase coherence into the Abrikosov state. This problem is simplified in two-dimensional case when the last gradient term disappears from the GL free-energy (18) and this relation becomes enough simple

$$\frac{F_{GL}}{k_B T} = V(\epsilon < |\Psi|^2 > + \frac{\beta_a}{2} < |\Psi|^2 >^2) \quad (26)$$

Since the F_{GL} value depends only on the average density of superconducting pairs $n_s = < |\Psi|^2 >$ and the Abrikosov parameter β_a the sum in the relation (18) for the veritable free-energy taken over the function substrate spanned by the LLL can be substituted on two integrals [44]

$$F = -k_B T \ln \left(\int_0^\infty dn_s \int_{\beta_a}^\infty d\beta_a N(n_s, \beta_a) \exp\left(-\frac{F_{GL}}{k_B T}\right) \right) \quad (27)$$

where $N(n_s, \beta_a) dn_s d\beta_a$ is a subspace volume with the given values of n_s and β_a . $\beta_A \approx 1.159596$, corresponded to the triangular vortex lattice [2], is the minimum value of the Abrikosov parameter β_a in the subspace spanned by the LLL.

The number of the eigenfunctions equals to the degeneracy number of the LLL, which equal in the dimensionless unit system to the area S of the two-dimensional superconductor, $V = Sd$. A given n_s values lie on a 2S-dimensional sphere with radius $n_s^{1/2}$. The area of this sphere is equals to $2\pi^S S! (n_s^{1/2})^{2S-1}$. It is important the β_a value does not depend on the n_s value. Therefore $N(n_s, \beta_a)$ is proportional to $n_s^{S-0.5} n(\beta_a)$, where $n(\beta_a)$ is a fraction of the 2S-dimensional sphere with the given β_a value.

The Abrikosov parameter has minimum value $\beta_a = \beta_A$ in S points of 2S-dimensional sphere. Each point corresponds to the triangular vortex lattice. The transition into the Abrikosov state takes place when the system comes to a stop near a point and can not come, because of thermal fluctuation, in other $S - 1$ points with $\beta_a = \beta_A$. One function from the Eilenberger function basis [35] gives main contribution to the thermodynamic average in the Abrikosov state. Whereas in the mixed state without phase coherence, when the system passes free between all S points with $\beta_a = \beta_A$ because of thermal fluctuations, all Eilenberger functions equal in rights and give the same contribution to the thermodynamic average. In a region of the 2S-dimensional sphere near $\beta_a = \beta_A$ the $\beta_a - \beta_A$ value is small and increases with moving away this point. There is a maximum $(\beta_a - \beta_A)_c$ value on the way between two points with $\beta_a = \beta_A$ on the 2S-dimensional sphere. The problem of the transition into the Abrikosov state can be reduced to the search of this critical value $(\beta_a - \beta_A)_c$. The transition takes place at $< \beta_a > -\beta_A = (\beta_a - \beta_A)_c$ [44]. It is enough easy to calculate the thermodynamic average of the Abrikosov parameter below H_{c2} at $-\epsilon \gg 1$:

$< \beta_a > -\beta_A \approx 2n_s^{-2} \approx 2(\beta_A/\epsilon)^2$ [44]. But it is much more difficult to find $(\beta_a - \beta_A)_c$. It was only shown for the present that a value $\beta_a - \beta_A > (\beta_a - \beta_A)_c$, at which the contribution from other Eilenberger functions is not small, is inversely proportional to superconductor size $S^{1/2}$ [44].

9. Why can the erroneous concept of vortex lattice melting appear and become popular?

The transition into the Abrikosov state is not described theoretically for the present first of all because of the wide popularity of the conception of vortex lattice melting. It may be that this conception is a greatest and most long-term delusion of modern physics. Hundreds of papers, including many papers with titles "Evidence of the vortex lattice melting ...", have been published in the last years in which the vortex lattice melting is considered. Many papers concerned to the vortex lattice melting are publishing up to now [119-174]. Therefore it is important to explain why this delusion appeared and remains very popular during a long time.

9.1. The conception of vortex lattice melting could appear because an incorrect interpretation of direct observation of the Abrikosov state.

According to most naive theories of vortex lattice melting the Abrikosov state is a flux line lattice (FLL) [60,61] like an atom lattice, or a lattice of long molecules [60]. The wide spread opinion that the Abrikosov vortex is a magnetic flux line appeared first of all because of direct observations [22,23] of the Abrikosov state. The magnetic flux structure can be observed only at enough low magnetic field where the persistent current around vortices induces an enough visible gradient of magnetic induction. In this case the Abrikosov vortex seems as a separate magnetic flux induced by the persistent current. Therefore most scientists interpreted the Abrikosov vortex first of all as magnetic flux line. But it was enough to bring up a question: "If the vortices are magnetic flux, why does not the magnetic flux disappear when the vortices disappear at the transition from the Abrikosov to normal state?" in order to understand that this interpretation is not quite correct. Also the question: "If the resistance in the Abrikosov state is induced by flux flow why does the flux stop to flow in the normal state?" casts doubt on the flux flow resistance.

Nevertheless the conception about magnetic flux line and flux flow resistance exercise complete sway during a long time. It could be possible since there are not manifest contradictions between the Abrikosov vortex as flux line and as singularity in the mixed state with long phase coherence if we consider only this state. It may be that the only difference is that the singularity and the magnetic flux should flow in opposite directions in order to induce a voltage with the same direction. But this question about the nature of the Abrikosov vortex becomes a matter of principle when the transition from the Abrikosov state to the normal state is considered.

When the vortex is considered as a flux line then most people neglect that the Abrikosov state is first of all the mixed state with long range phase coherence. The flux line is indeed like a long molecule and if it is seemed that these long molecules form a lattice then why this lattice could not melt.

9.2. *Could vortices be in the vortex liquid?*

If the vortex lattice melts than a state above this transition is vortex liquid. There is an important question: “Could vortices be in the vortex liquid?” The attitude to this question is different. Most experimentalist think that vortices should be in the vortex liquid because it is impossible to imagine a vortex liquid without vortices. Some theorists, first of all makers of theories of vortex lattice melting, do not love to answer on this question. But many theorists understand that vortices can not be in the vortex liquid. They say: “It is only name. We do not should debate about a name. It is not important”. But I can not agree that a name is not important. Just the history of the appearance of the conception of vortex lattice melting manifests that an incorrect name led to unfortunate results.

Some experts understood that the magnetic flux can not flow in the mixed state of type II superconductors. Nevertheless people read in all textbook [21,47-49] that the resistance in the Abrikosov state is induced by flux flow. Therefore the resistance dependencies observed in the “vortex liquid” regime are compared in many experimental work [106] with the theoretical dependence for the flux flow resistance. Such comparison has some grounds if the resistance is induced by flux flow. Magnetic flux is both in the Abrikosov state and in the “vortex liquid” regime. Therefore if the flux flows in the Abrikosov state then why can it not flow in the “vortex liquid”? But in this case it should flow also in the normal state above H_{c2} since no qualitative change takes place at H_{c2} . Thus, the incorrect name carries to the point of absurdity.

It is not important for the theories considering the energy dissipation at the vortex flow [67,175] what flows, magnetic flux or singularity. Therefore the authors of [106] and other papers could compare the experimental dependencies above the “vortex lattice melting” with the vortex flow resistance if the vortices are in the vortex liquid. Therefore the vortex liquid is not only name for the experimentalists which compare the experimental data with the vortex flow theory.

9.3. *Lack of information about absence of any phase transition at H_{c2} .*

Some experimentalists can compare the experimental results with a vortex theory since they assume as before that a phase transition occurs at H_{c2} . The knowledge about the mixed state of most scientists was formed by the influence of results of the mean field approximation. They thought that the second order phase transition into the Abrikosov state occurs at H_{c2} and that this state is first of all vortex lattice. Only few experts understood

in the seventies that thermal fluctuations changes qualitatively this notion. The situation became even worse after the discovery of HTSC in 1986 when many new people turned their attention to the fluctuation phenomena in the mixed state. Most scientists are no enough well-informed up to now that the results obtained in the seventies demonstrate clearly the absence of any phase transition at H_{c2} . The lack of this information is one of the most reason of popularity of the vortex lattice melting conception. Indeed, if a phase transition can be at H_{c2} then one can assume that the vortices disappear at the second critical field and the first order phase transition observed below H_{c2} is the vortex lattice melting. In this case the vortex liquid is indeed liquid of vortices as some experimentalists assume.

9.4. *Definition of phase coherence.*

But many theorists know that no phase transition can be at the second critical field and therefore understand that vortices can not be in the vortex liquid. They understand that vortices are singularities in the mixed state with long rang phase coherence and therefore the vortex disappearance should be a phase transition. Nevertheless these theorists do not repudiate the conception of vortex lattice melting. The reason of such attitude is the definition of phase coherence used by all theorists. If the phase coherence is defined through a correlation function, i.e. as coherence between two points, then long-rang phase coherence can exist in the Abrikosov state only if the crystalline long rang order of vortex lattice exists. In this case the vortex lattice melting is simultaneously the disappearance of long rang phase coherence. Then the conception of vortex lattice melting should not be rejected. But if the long rang phase coherence can not be without the crystalline long rang order then it can not be in any real Abrikosov state since as A.I. Larkin showed in 1970 [34] pinning disorders destroy the crystalline long rang order of vortex lattice. Moreover even short rang order phase coherence can not be in samples with strong pinning disorders in which the Abrikosov vortices are distributed chaotically. But in this case the vortices can not be also in the Abrikosov state since singularity in the mixed state with phase coherence can not exist without phase coherence.

Thus, the definition of phase coherence used for the present by theorists carries to the point of absurdity. It was shown by some theorists [176,177] that the phase coherence can be short-ranged even in the vortex solid state. This result means that not only the vortex liquid without vortices but even the vortex lattice without vortices are possible if the definition of phase coherence through a correlation function is used. Therefore the definition of phase coherence through the relation (21) should be used in the Abrikosov state. According to this definition the existence of phase coherence does not depend on vortex distribution, but only existence of vortices is evidence of phase coherence. The independence of long rang order on the existence of the crystalline long

rang order of vortex lattice means that the vortex lattice melting and phase coherence disappearance are different transition. The melting can be without the disappearance of vortices. And therefore the conception of the vortex lattice melting should be rejected on the base of the experimental data. If only first order phase transition is observed on the way from the Abrikosov state to the normal state then it is phase coherence disappearance since the existence of the long range phase coherence in the Abrikosov state can not be called in question in contrast to the vortex lattice.

The vortex lattice melting is not only name. All theories of the vortex lattice melting describe just vortex lattice melting. That is they describe the transition which does not exist whereas the first order phase transition observed in bulk high quality samples at $H_{c4} < H_{c2}$ is not described for the present. In order to describe this transition one should find at which parameters, temperature, magnetic field, superconductor size and others, the phase coherence defined by the relation (21) can appear. It is very difficult theoretical problem. According to this definition the long phase coherence exists in the Abrikosov state with any amount of pinning disorders. But the sharp transition can be expected to find theoretically only in superconductor with weak pinning. It is followed from the experimental and simple arguments considered above. The definition of phase coherence proposed here diminishes the difference between the Abrikosov and Mendellson's model. It is equally valid for the both models. The Mendellson's model but not vortex glass should be used for the description of the Abrikosov state with strong pinning disorders. The conception of the vortex glass [178-186] is only science fiction as well as vortex lattice melting. They are based on the same delusion. The vortex glass is not spontaneous glass as well as the vortex lattice. It is important to remember that the Abrikosov state is observed in an inhomogeneous finite space in contrast to crystalline lattice and glass.
